RUPTURE OF THE ESOPHAGUS RESULTING FROM EXTERNAL TRAUMATISM.*

By HOWARD E. LOMAX, M.D.,

ALBANY, N. Y.

ASSISTANT DEMONSTRATOR OF ANATOMY, ALBANY MEDICAL COLLEGE.

A perusal of the literature appertaining to injuries of the esophagus shows that there is some confusion as to the exact meaning of the term rupture of the esophagus. In this paper by the term rupture of the esophagus is meant a complete, defined solution of continuity, extending through the walls of this tube and occurring during life. This excellent definition is the one adopted by Fitz[1] in his admirable work, "Rupture of the Healthy Esophagus."

The object of this treatise is to deal more especially with ruptures of the esophagus as a result of external traumatism.

Solutions of continuity as the result of swallowing foreign bodies, together with their destruction of tissue by pressure or subsequent inflammation, will not be considered; nor will stab wounds resulting in perforation of the esophagus find any place, and lacerations of the esophagus by bullet wounds will be dismissed with the following rather remarkable fact: throughout our entire civil war there was but one case of bullet wound of the esophagus reported.[2]

Rupture of the esophagus resulting from external traumatism is extremely rare. This is due partly to its elasticity, mobility, and secluded position. Its situation in the posterior mediastinum, surrounded by blood-vessels, nerves, the thoracic duct, and lymphatic glands, bounded in front by the cushion-like construction of the lungs, and further defended by the sternum and spinal column acting as shields, imparts to this organ a most protected position from any external violence. The relaxed condition of the tube, its loose attachment to the pleuræ and surrounding parts, and its elasticity, act as additional guards, as these factors make it possible for the organ to be pushed away from any external influence that would result in its harm. A further factor in its protection is its posterior relations, the anterior convex surfaces of the vertebræ, and the thoracic aorta upon which it rests making a most excellent rounded base upon which to slide from side to side out of harm's way.

Rupture of the esophagus from external violence is thus so rare as to deserve careful consideration, and, from the fact that the literature of the subject is very barren, every case is worthy of record. This is especially true when the rupture has been positively recognized by post-portem examination and the record is accompanied by a full autopsy report.

The history of the case which serves as the nucleus of this paper is as follows:

Miss H. W., age 44, a mill-hand, was injured about 9 A.M., November 21, 1904, by having her body caught between the trap-door of a safety elevator and a brick wall. The space in which she was caught measured about nine inches, and the pressure was sufficient to break the door in pieces.

I arrived about ten minutes after the accident and found the patient sitting on a stool in a bent-up position and complaining of a dull pain in the lower left portion of the left mammary region. She was perfectly conscious, had not fainted nor vomited since the accident, and insisted that she was not hurt. A physical examination, however, showed a decided cyanosis, this cyanosis being especially well marked in the regions of the mouth, nose, ears, and fingernails. Respirations were 32 and labored; pulse 120, weak and somewhat intermittent, and temperature 98.6° under the tongue. Auscultation showed all heart sounds weak, but in normal locations; no abnormal dullness anywhere in the chest; respiratory sounds quickened, but otherwise normal. There was no fracture of the ribs.

There was an irregular bruised area over the left breast, in which the skin showed a blue discoloration. A linear laceration 7 cm. long was found, extending from the umbilicus upward and outward, and surrounding it was a quadrilateral area over which the skin was discolored, and in which were several vertical scratches running parallel. This laceration extended down to the transversalis muscle in such a manner as to loosen the internal oblique from the transversalis for a considerable distance. A hypodermic of nitroglycerin (gr. 1/50) and inhalations of ammonia seemed to clear up the cyanosis.

The possibility of an internal injury was fully explained to the patient, and I recommended that she be taken to a hospital. In spite of my advice, she flatly refused to be moved to a hospital, and it was a difficult matter to convince her that it was necessary for her to be taken to her home.

A more thorough examination, made at her home an hour later (10 A.M.), showed a pulse of 92, fair quality; respirations, 24, not labored, and temperature 98.6°; no cyanosis. She still complained of pain in the left side, but a careful examination failed to reveal anything abnormal save the skin discoloration. There were no fractures of the extremities, but while the patient insisted that she had no pain in the pelvic region, well marked crepitus could be detected on manipulating the pelvis. This crepitus was most marked at the symphysis pubis. Normal urine was voided at 9.45 A.M. On percussion, there was a well-defined dullness throughout the left inguinal and left half of the hypogastric region. Palpation elicited no tenderness in these regions. The body and extremities showed many bruises and abrasions.

The abdominal wound was rendered aseptic and closed with five interrupted catgut sutures. A firm bandage (such as is used after a symphyseotomy) was applied around the pelvis.

Realizing that no patient who has met with an accident likely to cause an internal injury should be considered safe until after the lapse of at least twen-

*Read before the Medical Society of the County of Albany. November 8, 1905.

ty-four hours, I ordered that this patient should be kept absolutely quiet in bed, and that she take no nourishment until I made my next visit. These directions were not followed. Soon after I left the house she sat up in a chair and in the afternoon partook freely of clam broth and milk. When I saw her at 5 P.M. she presented a most alarming condition. The face bore a most anxious expression; she complained of severe pain in the left of the thorax; respirations, 60, jerky, and accompanied by retraction of the suprasternal and supraclavicular spaces; pulse, 160, weak, thready; temperature, 99° (tongue).

Inspection of the chest showed exaggerated respiratory movements on the right side, with diminished expansion on the left. There was no displacement of the heart apex. Percussion showed marked flatness in the lower left region, the upper boundary of flatness changing according to the position of the patient. Respiratory sounds were greatly diminished, deep seated, or entirely absent over the flat area. Auscultation also showed exaggerated breathing over the right lung.

In view of the sudden onset of the above symptoms, I made a diagnosis of hemorrhage in the left pleural cavity; rupture of the esophagus, together with milk and clam broth in the left pleural cavity being entirely unsuspected. No positive diagnosis was made of the condition in the left iliac region.

The patient sank rapidly and died at 8 P.M., about eleven hours after the accident. During this interval of eleven hours she never vomited, nor did she complain of any pain except over the left mammary region. This pain was intensified in the recumbent position, the patient receiving the most comfort by sitting up with the body bent forward. There was no tumefaction in the supraclavicular region, nor was there any trace of an emphysematous condition anywhere. There was a slight cough following the accident. After taking the nourishment this cough was somewhat increased.

The patient had always been a hard-working woman, of good habits, an habitual small eater, and not an alcoholic. Her sister stated she had never complained of any stomach trouble and was not subject to vomiting. The accident occurred about two hours after her breakfast, which consisted of some crackers and coffee.

I am greatly indebted to Dr. E. MacD. Stanton of the Bender Hygienic Laboratory, who performed a very careful post-mortem examination. The following notes are from the autopsy protocol:

"H. W., white, age 44; service of Dr. Lomax. Body is that of a small-framed, well-nourished woman. Length of body, 152 cm. Rigor mortis present. Pupils equal. No edema present. Over the left breast is an irregular area, 9 x 3½ cm., in which the skin shows a brownish-red discoloration. On the abdomen, to the left of the median line and above the umbilicus, is a quadrilateral area measuring 8 x 10 cm., over which the skin is brownish-red in color and shows numerous parallel vertical scratches. Extending from the umbilicus through this area for a distance of 7 cm. is a linear laceration, closed by five interrupted catgut sutures.

"Abdominal cavity contains about 400 c.c. of apparently serious blood-stained fluid. At the middle of the transverse colon is an area 6 cm. in length, in which the subserous tissues show a reddish discoloration, together with several linear tears.

"Right pleural cavity contains approximately 500 c.c. of slightly blood-stained fluid."

"Left pleural cavity contains approximately 1,100 c.c. of dark, cloudy, straw-colored fluid, having a sour acid odor and containing numerous masses of soft, curd-like material. In the posterior mediastinal tissues, just anterior to the descending aorta, 2 cm. above diaphragm, is an irregular laceration 2 cm. in diameter, which opens in the left pleural cavity, and from which exudes a material similar to that found in the pleural cavity. A probe passed downward through the laceration passes through the cardiac orifice into the stomach and upward into the esophagus.

"Lungs and pericardial cavity negative.

"Heart negative, except some soldier's patches over right and left ventricles. Myocardium soft, grayish-brown in color.

"Pelvis: retroperitoneal pelvic tissues are filled with bloody exudate. At the symphysis pubis is a fracture extending along the line of symphysis, allowing a separation of ½ cm. A second line of fracture extends from the ramus of ischium. The third line of fracture extends along the sacro iliac junction.

"Anatomical diagnosis: Traumatic rupture of esophagus, with escape of stomach contents into left pleural cavity. Multiple fractures of the pelvis. Serohemorrhagic fluid in abdominal cavity and right pleural cavity. Multiple bruises of skin surfaces."

The specimen of the ruptured esophagus has been placed in the museum of the Bender Hygienic Laboratory, Class O, No. 807.

My interest in the case stimulated me to look up in the literature all reported cases, to refresh my knowledge of the anatomy of the esophagus and surrounding parts, and thus, after a due consideration of the anatomy and an impartial study of the reported cases, venture to explain why and in what manner this peculiar accident happened to the esophagus.

To this end several dissections were made and a series of experiments performed in the dissecting room of the Albany Medical College.

In searching for similar cases, the literature on wounds, ruptures, and perforations of the esophagus was found to be very voluminous; but, unfortunately, it was impossible, in most instances, to ascertain from the titles of the works whether the ruptures had been the result of external or internal causes. Hence, in order to review all cases of rupture as the result of external traumatism, it was necessary to go over the entire field. This necessitated a review beginning with the first case of rupture of the esophagus reported,[3] that of the celebrated Dutch Admiral, Baron Wassenaer, so minutely described in Latin by the renowned and much-beloved Boerhaave, and ending with the works of Whipham[4] and Dupas.[5]

Dupas' paper was published in a veterinary journal in 1903, and in the same year H. G. Simpson[6] published a paper on "Rupture of the Esophagus in the Horse." Simpson, Whipham, and Dupas are the latest contributors to the literature, their papers appearing in 1903.

A thorough review of a very extensive series of cases from all known sources shows there has been, up to this time, but one case on record which can be properly included under rupture from external traumatism. With the exception of a border-line case, all other cases are instances of ruptures from muscular action, perforations associated with various pathological conditions outside the esophagus, foreign bodies within this tube, or else they are cases of ante-mortem or post-mortem softening.

The case reported by Raiimondi[7] is particularly interesting, in that it is the only other case on record in which the esophagus ruptured as a direct result of compression of the thorax. The case also has so

many points similar to mine that a brief review follows:

M. G., male, age 39, lamplighter in a railroad station in the city of Siena, on the evening of November 14 (time not given) was caught between the bumpers of a locomotive and coach, one bumper over the epigastrium and the other over the back. When he arrived at the hospital, shortly after the accident, his breathing was rapid and superficial, and he complained of pain over the costal region. Face cyanotic. There was a contusion over epigastric region. Palpation revealed no fracture. Abdominal muscles much contracted and palpation produced much pain. Treatment consisted of ice to epigastrium and hypodermic of morphine. At 9 P.M. the condition was as follows: General condition worse. Emphysema in suprasternal and supraclavicular spaces. Respirations on right side abolished. Percussion on right side gave well-marked tympanitic sound, and on the left, normal sound. Respiratory murmurs abolished on right side; on the left side the respirations were rough and accompanied by a vesicular murmur. Raiimondi made a diagnosis of pneumothorax, bilateral, but more marked on right side. Later in the evening the cyanosis was more marked and the body was cold. Death occurred at 5.30 A.M., November 15. During the death struggle the breathing was very labored, and the emphysema had extended down to the inguinal regions.

Post-mortem examination revealed the following conditions: Rupture of esophagus, laceration of right pleura, passage of stomach contents into right pleural cavity, small lacerations of right lung and right-sided pneumothorax. Right pleural space contained about 1,500 c.c. of stomach contents; the left 250 c.c. of sanguineous material. Anterior mediastinum contained gas. The rupture of the esophagus communicated with the posterior mediastinum.

This rupture was situated on the right side of the esophagus, about 8 cm. above cardia, ran in an oblique direction, and measured about 3 cm. The autopsy also revealed several small, ecchymotic spots in parietal and visceral peritoneum. There was a well-marked emphysema extending from the neck to the lower part of abdomen.

From the autopsy findings, Raiimondi considers the rupture of the esophagus the primary lesion and the lesion of the right lung as consecutive. He considers as causes of death, collapse of lung, blood in left pleural cavity, and liquid and semi-liquid contents in right pleural cavity. As to the cause of the rupture, he expresses the following view: "The rupture was the result of pressure of the thorax, while the esophagus was full of gas and liquids, the pressure being sufficient to rupture the esophagus at its weakest point."

T. R. C. Whipham[4] reports a case of rupture of the esophagus from an accident, and as this might be considered a border-line case, the following brief history is given: This case occurred in a man, age twenty-seven years, who had been thrown from a horse. There was a fracture of the skull. The left pleural cavity contained about a pint of fluid and semi-fluid masses. The fluid had the sour odor of beer and the contents of the left pleural cavity was evidently food. A rupture, evidently of recent origin, was found on the posterior wall of the esophagus, communicating directly with the left pleural cavity. The rupture was situated just above diaphragm, measured about one and one-half inches, and was directed longitudinally. There was no sign of a previous lesion.

Whipham expresses two views as to the cause of this rupture. First, a sudden muscular contraction of the pharynx, causing an obstruction to the forcible ejection of food from the stomach, and hence a rupture. Second, that the esophagus was over-distended by the man turning a half somersault while his forehead remained in contact with the ground, in which case the esophagus would have been stretched over the cervical vertebræ, with a rupture as a result. The experiments of von Zenker and von Ziemssen,[8] which will receive full notice later, prove that this second theory is based on impossibilities, and that the first theory is nearer the truth.

While this case of Whipham's was due to an accident, it must be considered as a border-line case of rupture of the esophagus as a result of external traumatism, because the rupture was not the initial lesion. Here the initial lesion was the fracture of the skull. This fracture, with a full stomach, caused vomiting, and the vomiting in turn caused the rupture. The fracture was the primary lesion and the rupture a consecutive one, brought on during the vomiting.

Some writers on rupture of the esophagus are extremely critical and seem to demand much exact evidence before they are convinced that a true rupture has occurred. A few authorities have rejected certain cases as genuine ruptures, while other authorities have accepted the same as true cases of rupture.

In order that all critics may be satisfied as to the genuineness of my case, it will be necessary to produce some positive evidence.

King has called special attention to the frequency of cadaveric softening of the esophagus; but the rupture in my case could not have been the result of cadaveric softening, as the cold weather and short time between death and autopsy would prevent any very marked post-mortem change. Furthermore, there was no evidence of cadaveric softening in any of the internal organs.

Some authorities have rejected cases on the ground that they were instances of post-mortem digestion. The sharp, well-defined tear and the clinical evidence of fluid in the pleural cavity before death would exclude this, and, on the same grounds, we may exclude softening of the coats from peptic solution in the last hours of life.

The autopsy failed to reveal any evidence of adherent caseous glands, aneurysms, with their accompanying erosions, or malignant ulcerations; nor was there any evidence of an antecedent varicose condition of the esophageal veins, and a careful examination could not detect any trace of an agonal esophagomalacia within the tube. The sharply defined edges of the rupture would also go to prove that a gastromalacia was in no way responsible for the rupture. The clinical history and the above evidence conclusively prove that the rupture occurred in a healthy esophagus, that it took place intra vitam, and that it was the direct result of an external traumatism.

The etiology of all ruptures of the esophagus is indeed a moot point and gives rise to much speculation. That we may form a better conception of the exact manner in which rupture as the result of external traumatism takes place, it is necessary for us to view the whole subject of rupture in its different aspects and relations, and to consider attentively all the data, verified by facts and experiments, gathered from the literature concerning injuries to the esophagus.

To begin with, causes of rupture may be divided into three classes: (1) Those that arise from vomiting. (2) Those that are the results of traumatisms

arising within the tube. (3) Those that arise from external traumatism.

Most authorities admit that the esophagus can rupture spontaneously; in which case the rupture is due to vomiting or to a severe shaking up of the body, as from jumping out of a wagon. Of the spontaneous ruptures McWeeney[9] has reported seventeen undoubted cases in which there was an apparently healthy organ. On the other hand, von Zenker and von Ziemssen[8] have demonstrated that the so-called spontaneous ruptures occur in organs weakened by an autodigestion, so that any force acting within or without the tube may cause a tear of the same. The rupture would then take place as a result of any severe mechanical force, as a sudden compression of the thorax. Any force, even the mere contraction of the organ itself, might cause a tear in its walls.

As an additional cause, we may add muscular action: for Fitz[1] has produced evidence which proves that a previously healthy esophagus may be ruptured by muscular action. This seems to be doubted by many. On this point Dr. Douglas Powell[10] says, "It is difficult for an esophagus to rupture unless the nutrition of its coats was previously interfered with."

The case I have reported is unique in many ways. First, it was not the result of vomiting; second, it was not a spontaneous rupture; third, it was not due entirely to muscular contraction; fourth, it occurred in a healthy tube, and fifth, it was a direct result of a compression of the chest walls.

No very great external force would be required to rupture the esophagus if the walls of this tube were weakened by any constitutional disease, providing the stomach or esophagus was full of gas or food when the accident happened.

In 1882 Mr. Stanley Boyd[11] exhibited two specimens of rupture of the esophagus in both of which there had been a severe constitutional disease which weakened the walls of the tube. One case occurred in a woman aged eighteen years, in which the esophagus and gastric mucous membrane showed the recognized signs of self-digestion, superinduced, probably, by a preceding Addison's disease of seven months 'standing. The other case occurred in an infant of four months, who had had an erysipelas and peritonitis following an operation for strangulated undescended testicle.

If in these two cases a rupture followed as the result of mere vomiting, one can easily see how a rupture would result if the thorax had been suddenly squeezed while the stomach or esophagus was full of gas or food.

In speaking of spontaneous rupture McWeeney[9] says: "The rupture is due to, first, softening of the coats, and, second, sudden increase of pressure from within." In the external traumatic cases there is a double pressure—one from within and one from without.

Any disease within the esophagus that will act as a cause of spontaneous rupture will predispose the esophagus to rupture from external violence. It is a well-known fact that the esophagus is less protected against the action of the gastric juices than the stomach, undoubtedly, on account of its much less abundant blood supply. The action of the gastric juice and the circulatory changes to which the lower part of the esophagus is subject, namely varicose veins and accompanying thrombosis, give rise to a true intravitam esophagomalacia.

Von Zenker and von Ziemssen[8] have shown that this esophagomalacia is due to the following prerequisites: (1) Presence of stomach contents rich in pepsin and acid; (2) regurgitation; (3) protracted retention of regurgitated food in the esophagus; (4) sufficient warmth; (5) cessation or great weakness of the circulation.

Any disease of an organ adjacent to the esophagus, whereby its walls would become weakened, would also predispose it to rupture from external traumatism. In this connection may be mentioned aneurysm, cancer, abscess, and tuberculous glands, with the erosions and ulcerations with which they are so frequently associated.

And again, any external traumatism that will give rise to severe and protracted vomiting may cause a rupture. Vomiting as a cause of rupture is an interesting one, and calls for some careful study. That vomiting is a notorious cause of rupture has been proven by many cases, notable of which is the one reported by John Griffin,[12] who summarizes as follows: "There can be no doubt that the violent effort of vomiting had forced a large quantity of the contents of the stomach suddenly into the esophagus, thus causing rupture." Mackenzie[13] and Voiss[14] have given vomiting much careful consideration, and have advanced explanations of much import.

Mackenzie considers that the immediate cause of spontaneous rupture is vomiting, and that vomiting never causes rupture unless the stomach contents cannot be expelled through the esophagus at the same rate that the contents leave the stomach. He states that this is due to a temporary obstruction near the upper end of the gullet, which prevents the outward flow from the stomach. This obstruction may be due to something inherent in the esophagus, such as food, or to a strong contraction of the circular fibers situated at its upper part. In other words, there is a lack of coordination of the muscular action of the esophagus.

Herbert J. Voiss, in his inaugural dissertation[14] (p. 28) has pointed out that when vomiting is the cause of rupture the process is as follows: The circular muscular fibers are relaxed while the longitudinal fibers are contracted; thus there is a shortening of the tube and it is drawn upward. When the abdominal pressure is exerted the stomach contents are driven forcibly upward against the cordia, and there is a flattening of the diaphragm. The contracted condition of the longitudinal fibers (shortening of the tube) and the marked flattening of the diaphragm give rise to a tear of the esophagus. As a result of this tear, the circular muscular fibers contract above the diaphragm, narrow or obstruct the passage upward of the stomach contents, and the contents go sideways through the esophageal wall. He further states that if the vomiting increases and becomes severe, viz., to the point of tetanic regurgitation, the process becomes an extremely painful one.

As regards the location of the rent in the tube, it is a curious fact that in all the reported cases the rupture, with the single exception of one instance, has occurred in the lower third of the tube. In this one exception the rupture occurred at the level of the bifurcation of the trachea. Of the seventeen cases reported by McWeeney[9] one rupture extended to the stomach.

Another singular fact is that, with the single exception of the case reported by Boerhaave, the rupture has invariably been in a longitudinal direction. In Boerhaave's case the rupture was a transverse one; the esophagus was torn completely across, so that the two parts were drawn respectively upward and downward.

The similarity in the location and direction of the rent in so many cases has stimulated investigators to experiment in order to arrive at a possible explanation. Mackenzie,[13] by experiments, has shown that direct pressure within the esophagus gives rise

to a longitudinal tear; that the tear never takes place in the upper part of the tube, is generally confined to its lower third, and that the muscular wall offers less resistance than the mucous.

Brosch[15] and Bowles and Turner[16] have also proven by experiments that the lower third is the weakest part of the tube, and that its posterior wall is the weakest of all. Their experiments consisted of increasing the pressure from within by means of either gases or fluids. The involuntary muscular fibers, which alone constitute the muscular structure of its lower portion, may account in a measure for the weakness at its lower part.

The experiments of von Zenker and von Ziemssen[8] (p. 96) show that the muscular wall offers less resistance than the mucous. Their experiments also show that the esophagus can stand a considerable amount of stretching, and that this stretching can be kept up for quite a length of time. In one experiment the esophagus bore a weight up to five kilograms without tearing. Before stretching, the tube, between the bands, measured seventeen centimeters. It stretched to twenty-four centimeters before it showed any evidence of a tear; and then, after a weight of five kilograms had been used for almost one minute, the thin cellular coat and the muscular layer tore in a circular direction and retracted from the underlying mucous layer. All this time the mucous membrane remained uninjured. A further experiment showed that the mucous membrane withstood a weight up to ten kilograms for several seconds before it gave way. It stretched considerable and then tore in a ragged circular direction.

No one has apparently explained the accompanying laceration of the pleura, which is so loosely attached to the esophagus. The laceration of the pleura is probably due to direct pressure.

Some experiments were conducted in the dissecting room of the Albany Medical College, in order that we might the better explain the manner in which an external traumatic rupture takes place. These experiments were, however, entirely untrustworthy because of the various conditions brought about as the result of death. We were experimenting on bodies in which life had been extinct for some time; the various tissues were more or less hardened from the action of formalin, and the collapsed lungs, stomach, and intestines did not lend the same support to the esophagus as in life. The circumstances, therefore, were so unlike those found in life that no definite conclusions could be scientifically proven, and it would be useless to mention these experiments. The dissections did show, however, that the lower part of the esophagus is more movable than is generally supposed; that the tube as a whole can be stretched longitudinally, and that in the posterior mediastinum it can be pushed from side to side without injury to itself or neighbors.

The bulk of evidence obtained by many dissections, together with an extensive study of the mass of facts gathered from the literature, appears to support the view that when the esophagus ruptures as the result of external traumatism, the rupture is due to a double pressure; one from without and one from within the tube. Both of these pressures are brought about by a squeezing process. This squeezing process forces gas or food out of the stomach in the direction of least resistance. The action of the pyloric valve prevents, to a very great extent, any exit from the stomach in that direction; the cork-like effect of the food producing a further barrier as the food is suddenly wedged up against the pylorus. Thus the contents of the stomach are forced upward. At the same time there is a lack of coordination of the muscular structure of the esophagus, brought on by fright, pressure of the esophagus or injury to the pneumogastric nerve, and the circular muscular fibers of the upper part of the tube are suddenly contracted, and there is a temporary obstruction near the upper end of the gullet which prevents the contents of the stomach from being expelled from the esophagus at the same rate as they enter the tube. This obstruction is probably fortified by a sudden contraction of the pharyngeal constrictors, and the food itself blocks up the upper exit. The esophagus is thus violently distended in a balloon-like manner, and there is thus much pressure from within. This squeezing process also gives rise to an external pressure. The thorax is caught between two forces tending to meet. One force is applied to the spinal column or vicinity, and the other to the anterior thoracic region or epigastrium. The force coming from behind is restricted to some extent by the spinal column, but the force coming from in front does not meet with the same resistance. Owing to the elasticity of the ribs and costal cartilages, the sternum and thoracic wall are pushed backward, and the lungs being full of air, the heart is made to approach the spinal column. By this external pressure the already overdistended esophagus is compressed between the heart in front and the spinal column behind, and, as both outlets are closed, the food or gas is forced in the direction of least resistance, viz., through the esophageal wall at its lower third. Some of the esophageal contents would be pressed upward; but it is reasonable to suppose that most of the contents would be driven downward with such force that they would enter the posterior mediastinum or either pleural cavity.

If the force from in front meets the epigastrium in place of the anterior thoracic wall the stomach contents are driven with great force into the esophagus, the diaphragm is pressed upward, the capacity of the thorax is very much diminished, and the overdistended esophagus ruptures as the result of pressure from all sides.

Three forces, therefore, enter into the etiology of external traumatic rupture: First, pressure from without; second, pressure from within; third, muscular contraction. Pressure from within cannot take place unless the stomach contains gas or food. It is altogether likely that the rent takes place first in the muscular and cellular walls, and that the mucous membrane is the last to rupture.

In the case I have reported the clinical history would suggest that the stomach contained gas, with little food, and that the gas alone was responsible for the internal pressure. The physical examination and autopsy demonstrated that the material found in the left pleural cavity was food taken subsequent to the accident: the food passing through the rent directly into the pleural cavity.

In view of the fact that the rupture is seldom recognized during life, a detailed narration of the symptoms is particularly called for. In my case there were hardly any symptoms which might be considered as directing exclusive attention to the esophagus, and it was, therefore, exceedingly puzzling to make an exact diagnosis. The sudden tearing pain and the sensation of injected fluid noted in ruptures from internal causes are not of much import when the rupture is the result of an external traumatism, as the severity of the external blow is sufficient to mask the above symptoms. The two symptoms, dyspnea and cyanosis, seem to go hand in hand. The cyanosis is most marked in the region of the face. The breathing is rapid, superficial, and may be performed exclusively by the diaphragm. The characteristic position, the patient sitting up

with the trunk stooped forward, is probably due to genuine orthopnea. The simultaneous disturbance of respiration and circulation is so suggestive of a lesion in the vicinity of the pneumogastric as to demand some review of the anatomy and physiology of this nerve.

My dissections lead me to confirm the belief that much of the severity of these urgent symptoms depends upon the degree and extent of the injury to the pneumogastric nerve. It is to be recalled that the pneumogastric, with its plexiform arrangement (plexus gulæ), is intimately associated with the esophagus, the right and left nerves uniting along its anterior surface to form the plexus; this nerve, together with its communications with the cervical sympathetic, forming a plexus which is situated between the two muscular layers, and a second one situated in the submucous layer. Groups of ganlionic cells are found in each plexus. The esophageal branches of the pneumogastric are quite numerous, some being distributed above, but the largest and greatest number being distributed below. Its many branches, their intricate communication with other nerves, and their extensive distribution, make this one of the most important of the cranial nerves. It is both a sensory and a motor nerve, its sensory and motor fibers being distributed to the organs of voice and respiration, while the pharynx, esophagus, stomach, and heart are supplied by its motor fibers. Its functions are as varied as its distributions. It has an influence on deglutition, stomach and pancreatic secretion, respiration, heart action, and a marked trophic influence over the lungs. When we come to realize the importance of this nerve, especially when coupled to the sympathetic, and consider its intimate association with the esophagus, it is not unreasonable to suppose that the dyspnea and cyanosis are accountable to some lesion of, or shock to, this nerve.

In this connection one may not be far out of the way in supposing that the loss of coordination in the esophageal muscular fibers is due to the same cause, and that a sudden contraction of its upper circular fibers is brought about by a temporary loss of function of the pneumogastric.

Collapse is a very characteristic symptom, and while in this stage the face bears the hippocratic countenance and the features denote anxiety. The extremities are cold, and copious perspiration, especially from the neck and face, is common. The pulse is small, weak, and may be intermittent. The expression of the face shows the patient to be in a painful state of mind, and the fear of impending death, with its accompanying depressed condition of mind, may act as a psychological cause of this collapse. Certain it is that hemorrhage is not an etiological factor. Acute sepsis can be assigned as a cause, providing the patient lives long enough for sepsis to develop; and here it is well to remember that an acute sepsis can occur without necessitating any rise of temperature. Collapse may be charged to some severe injury of the lung or pleura. For instance, if the esophagus and pleura are both injured to such an extent that there is a marked hydropneumothorax, collapse may develop as the result of a suddenly compressed lung.

Voiss[14] says: "Collapse is probably due to injury to the vagus nerve, whose stimulation or paralysis may very readily occur because of its exposed location." This undisputed statement of Voiss must be considered as having much weight.

In spite of the fact that vomiting is generally looked upon as an early manifestation of rupture, it was not present in my case, and no mention of vomiting is made in the case reported by Raiimondi. While a study of all the reported cases of rupture shows that vomiting is the rule, in quite a few cases vomiting has been entirely absent. When vomiting has taken place it has probably had considerable to do with the cause of the rupture. If there is vomiting it generally ceases at the onset of collapse, and collapse without any further vomiting is a very important sign, although Allen's case (quoted by Voiss) shows that vomiting can continue indefinitely. Vomiting of blood is of little or no value as a symptom of rupture, as the blood is more than likely to come from the lungs.

Emphysema is a very important symptom. Owing to the close relation of the trachea, esophagus, and posterior mediastinum, emphysema is more likely to occur if the trachea has been involved in the rupture. However, there can be well-marked emphysema in the absence of any very great lesion of the lung. While emphysema is very often attributed to rupture of the lung, M. Louis (quoted by C. Colegrove[17]) declares that it may happen independently of any rupture of the lungs.

Colegrove also appends the following interesting paragraph from Dorsey's Cooper: "We may infer that from a mere rupture of a few of the bronchial cells, occasioned by irregular action of the lungs, or some other internal cause, a spontaneous diffusion of air may take place in the cellular texture of the body. Such examples are dependent on the same cause as emphysema from injury of the lungs, only the rupture of the bronchial cells in the former cases is less obvious."

Emphysema requires air and then sufficient pressure to drive the air forward into the surrounding tissues. The air may come from the lungs, in which case it is partly aspirated by the negative pressure of the lungs. It may be swallowed by the patient and enter the tissues directly through the esophageal rent, or it may enter the stomach and be forced through the rent as the result of vomiting, in which case gas from the stomach would make up part of the emphysema.

At any rate, the air or gas takes an exit through a false passage and enters the posterior mediastinum. When once in this space it is driven upward for want of opposition; the expiratory pressure, which is increased by coughing or vomiting, being sufficient to drive the air along from the posterior mediastinum into the tissues of the neck. Tumors, abscesses, and the like, when situated in the vicinity of the posterior mediastinum, would have a tendency to oppose the passage upward of air, and would tend to limit the emphysema. Severe pain also has a tendency to lessen emphysema because pain restricts respiratory pressure.

The first indication of an emphysema is a tumefaction, which appears in either supraclavicular region. This swelling soon becomes markedly emphysematous, constantly increases, and may spread over the entire body. This symptom is not always present. In my case it was absent, although a diligent search was made for it. In the case reported by Voiss its absence was possibly due to the very superficial respiration, slight cough, and no vomiting. In quite a few cases (notably Allen's) the emphysema has extended over the whole body. It would seem from the reported cases that the behavior of emphysema depends to some extent upon the severity of vomiting.

Cough is not a constant symptom, but when present is very painful.

Deglutition is not particularly disturbed; fluids may be easily swallowed and without apparent discomfort. As a rule, there is a diminished quantity of urine. Increased dyspnea and collapse close the

scene, death claiming the victim within twenty-four hours.

Notwithstanding the fact that the history, symptoms and physical signs have closely resembled each other in all reported cases, a diagnosis of rupture of the esophagus is seldom made. The condition is so rare that the medical attendant is entirely off his guard and does not suspect an injury to the esophagus; and the text-books give him no assistance, as the most of them are absolutely silent on the subject. A noteworthy exception, however, to this book silence is the short but well-written article by von Hacker,[18] to which I would refer interested readers.

Hamburger[19] says: "The diagnosis of rupture of the esophagus is first made upon the corpse, and often contrary to all expectations," to which may be added the words of Fitz, "even then the diagnosis may be attended with very great difficulties."

One of the objects of this paper is to present the case in such a light that a diagnosis can be more readily made in future cases. A résumé of the symptoms shows that vomiting, collapse, cyanosis, dyspnea to the extent of orthopnea, and emphysema are symptoms of the first rank.

The above symptoms, then, would lead one to suspect a rupture in all cases in which there had been an accident likely to cause a sudden violent compression of the thorax. Extreme precordial oppression, acceleration of pulse, severe pain, either fixed or situated in the course of the esophagus and increased by movements of the spine, would give additional ground for suspicion. Finally, a diagnosis of this rare condition can be made with some degree of certainty if to the above symptoms a physical examination of the chest shows evidence of a pneumo-hydrothorax or a more or less collapsed lung.

A sufficient amount of stomach contents in either pleural cavity would give practically the same physical signs as if the cavity contained a serofibrinous effusion, a serous transudation, pus or blood. Hence, it is of paramount importance that the physical examination include a careful use of the stethoscope, and that we bring to our aid the valuable means of inspection, palpation, percussion, and succussion. The use of Hamburger's auscultatory phenomena,[19] consisting of the extinction of the sound produced by swallowing, at the point of rupture, accompanied by a whistling noise, ought not to be adopted, because the material swallowed would pass through the esophageal rent and further damage the surrounding organs.

Secondary complications are rare. Were the patients to live long enough, we would expect such complications as acute emphysema, with a possible secondary gangrene of the lung; or lobular pneumonia from the entrance of food, blood, or pus. If the opening extended into the pericardium, a pyopneumopericardium might result.

The prognosis should be well guarded in all injuries to the chest; and no patient who has met with an accident likely to cause an intrathoracic lesion should be considered safe unless, after the lapse of at least forty-eight hours, he presents a normal pulse, circulation, respiration, and temperature, has had no protracted vomiting, and a rigid physical examination fails to discover any abnormal condition. If there be the least evidence of a ruptured esophagus, the prognosis is to be particularly guarded, as the accident has hitherto been invariably fatal. Its fatality is based partly on the fundamental rupture and partly on the accompanying injury to neighboring organs; and here one must not forget the secondary lesions in surrounding organs that will eventually follow in the wake of the rupture.

The most serious and dangerous elements are shock, collapse of the lung, laceration of pleura, with the presence of blood, and liquid or semi-liquid stomach contents in pleural cavity.

The symptomatic treatment of ruptures, the treatment hitherto followed, consists in lessening pain and introducing food and water into the system by high rectal injections. The introduction of food and drink per mouth is to be entirely suspended for three reasons: First, to prevent their entrance into the rent; second, to ward off further complications to the neighboring organs, and third, to facilitate the closure of the wound.

Voiss advises lessening the pain until death occurs. This advice was given in 1881, before Nasiloff drew attention, in 1888, to the feasibility of opening the thorax posteriorily for the purpose of reaching the esophagus and bronchi in cases of persistent obstruction by foreign bodies, and before the labors of Potarca, Quenu, Hartman, Bryant, and Curtis showed that non-malignant involvement of the posterior mediastinum is possibly amenable to surgical treatment. The modern surgery of the mediastinum, which tends to show that the thorax can be opened in front or behind, not only for the removal of foreign bodies in the esophagus or bronchi, but for the relief of disease processes in the mediastina, warrants a hope that surgery may yet successfully intervene in cases of rupture of the esophagus.

Posterior thoracotomy, as planned by J. D. Bryant, the technique of which was presented to the American Surgical Association in 1895, while not intended for rupture of the esophagus, is perhaps the most practicable operation for rupture of this organ. An operation for the repair of the rent would, however, require a much larger flap than is recommended by Bryant. A full account of Bryant's operation is found in his "Operative Surgery,"[20] where he also gives full details of Curtis' operations.[21]

In spite of the advance made in the surgery of the chest, any operation done for the relief of a ruptured esophagus will necessarily present many complicated problems for solution. The first obstacles met are the alarming condition of the patient as the result of the initial injury and the difficulty in determining the exact location of the rent. The condition demands much precision and rapid work, both of which are almost impossible. Delays in the operation, caused by collapse of the patient; the risks of hemorrhage, which are enormous; and collapse of the lung, brought about by opening the chest, are all elements which tend to further overcome the patient. Collapse of the lung and pneumothorax when the chest is opened, which are, unfortunately, serious and dangerous elements, may possibly be prevented by operating in a room with high-air pressure.

From the difficulty in promptly closing the opening an accompanying laceration of the pleura greatly increases the danger, and the operation becomes exceedingly embarrassing, owing to the inability to scrutinize the parts, and the respiratory movements of the lungs makes stitching of the lacerated pleura a procedure of much discomfort on the part of the surgeon.

Then again, the location of the rent is a very great barrier to a successful operation. The esophagus generally terminates somewhere in the vicinity of the tenth dorsal vertebra, and the rent is almost always situated at the lower third of the tube, the very situation which would present the most difficulty in reaching the organ. Bryant calls attention to the fact that operations below the ninth dorsal vertebra are not justifiable, owing to the great dif-

ficulty and increased danger of exposing the esophagus at this situation.

I am greatly indebted to Drs. A. Vander Veer, MacDonald, and Elting for valuable literature loaned me in the preparation of this article; to Dr. E. Mac D. Stanton for a most painstaking post-mortem examination and report, and to Drs. Craig and W. F. Hale for the use of dissecting-room material—to all of whom I wish to express my sincere thanks.

NOTE. The above is not a complete bibliography of ruptures of the esophagus, but is simply a list of works that have been particularly appealed to in the preparation of this article.

ACUTE YELLOW ATROPHY OF THE LIVER FOLLOWING ECLAMPSIA.

By L. T. ROYSTER, M.D.,

AND

CHARLES R. GRANDY, M.D.,

NORFOLK, VA.

THE rarity of this disease makes it extremely interesting and necessarily causes accurate knowledge to be very limited. Judging by the amount of literature on the subject, the occurrence of acute yellow atrophy is of great infrequency, for up to a very recent date not more than a dozen cases had been reported in this country, and Osler states that he has seen but two cases. It is to be presumed, however, that the disease is commoner than is thought, and it is more than probable that as more is known of it we will find a large number of cases repored.

The etiology is obsucre. and what has been written on the subject is largely speculative. The record of any case, however, adds something to our knowledge and contradicts or corroborates existing theories. I regret very much that the case here reported is not more fully recorded, but it is difficult to keep an accurate account of phenomena when working on a case of this kind outside of a well-equipped hospital and in the absence of well-trained assistants. I have endeavored to give as careful and concise account of the case as was possible under the circumstances, hoping that by adding this report to the literature already at hand something may be learned concerning this very obscure subject.

Among the predisposing causes of both eclampsia and yellow atrophy, illegitimacy and mental strain are given as being important. If this is true, the subject of this report was doomed to this end, since she was pregnant by the husband of her own sister with whom she lived and from whom she was striving to keep the knowledge of her condition.

L. J., 22 years old, unmarried, pregnant for the first time. Family history negative. Previous history without event. I had calculated her delivery to be due about June 5, 1903. On May 4 there was some edema of the ankles and lower part of the leg, but no nervous symptoms. I put her to bed, ordered milk diet and cream of tartar, and had a specimen of urine sent to my office. This was absolutely negative. On May 7 all traces of edema had disappeared and she was allowed to go about again. She remained free from trouble until May 18, at which time the nurse reported the legs again edematous; this time the swelling extended nearly to the groin and had come on during the night. I instituted the same treatment and ordered another specimen of urine.

May 19.—Urine of day before showed about 2 per cent. albumin by Esbach's test but no casts from a centrifuged specimen. No nervous symptoms except marked pain in the small of the back. Vaginal examination revealed a very soft and nearly obliterated cervix.

May 20.—Urine showed 7 per cent. albumin. At 9 A. M. there were pronounced labor pains. External os admitted two fingers. No further nervous symptoms. There was vomiting at 5 o'clock and at 8 P.M. the external os was fully dilated and membranes bulging. I ruptured the membranes, and in a few minutes the head was on the perineum. I took the pulse at this moment and found it to be 80. She was having good pains and the head was plainly visible, when she informed me that she was entirely blind, and before I could administer chloroform she was having a hard convulsion. I telephoned to Dr. Hargrave, and while we were making some necessary preparations the patient had several hard and effective pains and also another convulsion. I applied forceps and delivered. The pulse at this moment was 140.

We used hypodermics of fluid extract of veratrum viride, but the specimen in our possession was evidently a poor one, since it failed to reduce the pulse. In the meantime the patient had three convulsions in rapid succession, although we thought she was well narcotized. We then bled until the pulse was 70. Having secured in the meantime a better specimen of veratrum viride, we brought the pulse to 60 and kept it there by the administration of the drug at intervals of about four hours. Ten grains of jalap was then administered, and in due time profuse purging resulted.

May 21.—Urine contained 2 per cent. albumin. The total quantity of urine had increased markedly, although it could not be measured because much of it was passed involuntarily. In the afternoon the temperature rose to 103°, but fell to normal within an hour. From this time on the patient's condition

improved steadily, the blindness clearing gradually, and the mental condition clearing up until the following night, when she had a convulsion at 8 P.M. Dr. Hargrave and I then called in Dr. Grandy, and it was decided to stop the veratrum, which we were administering in 5 minim doses at intervals of four hours, for we thought this convulsion might possibly have been due to its toxic effect on the kidney. I ordered bromide of sodium in doses of 40 grains given every four hours through the night. She spent a comfortable and uneventful night. In the morning (May 23) the urine contained 1½ per cent. albumin and gave a strong reaction to the bile test. No leucin or tyrosin could be discovered. She was markedly jaundiced at this time. I suspected yellow atrophy and stopped all medication. During the day her condition grew steadily worse, vomiting and purging alternately. Ecchymotic spots appeared on the skin and by night she was delirious, tossing about the bed. Pulse, 120; temperature, 100°. This delirium continued until morning, when she quieted down, and about the middle of the day coma set in. Respiration was labored; pulse weak and rapid; complexion a dark oak. A large number of ecchymotic spots appeared on the skin, and for two hours prior to death there were violent passages of bloody stools. She died at 11 P. M.

Pathological Report by Dr. Grandy.—An incomplete post-mortem examination was allowed, and Dr. Royster found:

The *skin* and *sclera* deeply jaundiced, with ecchymoses in various parts of the body. The spleen was enlarged and soft. The kidneys were somewhat enlarged and pale. The *liver* was much smaller than normal, indeed not half its actual size; its capsule loose and puckered; its consistence soft, feeling much like lung tissue; its color rather a deep yellow, with occasional spots of red, while the gall-bladder was empty. A piece of liver tissue was placed in formalin and turned over to me for microscopic examination.

In places the liver cells had entirely disappeared and were replaced by a grandular detritus, containing a good amount of pigment. In other places the outlines of the cells were maintained, but their protoplasm was almost entirely replaced by what appeared to be fat droplets. In other places the liver cells appeared practically normal. The connective tissue was not increased, and the gall-passages were empty and had not proliferated. Though there was no general infiltration of round cells, there were often heaps of these in the neighborhood of the vessels. The larger part of the sections was composed of the granular detritus and the degenerated cells, described above, the latter being apparently in excess, while the well preserved liver cells did not form more than 10 per cent. of the specimen.

These findings, though very incomplete, are those of acute yellow atrophy of the liver. The clinical history at the end of the case also pointed to this disease, while the earlier symptoms were those of an ordinary case of puerperal eclampsia, which was apparently improving, before the symptoms of acute atrophy developed.

The question naturally arises as to whether we have to do in such cases with two distinct diseases, the acute atrophy following the eclampsia, just as diphtheria may follow measles, or merely with two stages of the same trouble. Recent writers seem to be coming to the latter conclusion. Thus Rolleston says, "It is not improbable that the discrete focal necrosis of the liver, seen in eclampsia, represents in a lesser degree or in an earlier stage the changes of acute yellow atrophy"; and Edgar, that eclampsia and acute atrophy may appear as two of the severer expressions of the toxemia of pregnancy. While we have every reason to agree with these two authorities, it may, nevertheless, prove interesting to compare the findings in eclampsia and acute atrophy, more especially as cases, in which both conditions are well marked, are extremely rare.

The pathological findings in cases of puerperal eclampsia, which have come to autopsy, have been far from constant. The liver shows the most constant changes, which are said by Schmorl to be characteristic. These consist of irregularly shaped reddish or whitish areas, scattered throughout the organ. Under the microscope they are recognized as areas of necrosis or degeneration, in which blood cells may or may not be present. These areas vary in size and sometimes can be discovered only with the aid of the microscope (Whitridge Williams). In acute atrophy we find similar areas, in which the liver cells have disappeared, but they are much larger than in eclampsia, and may or may not contain blood as in the latter. Then there are cells which have not been completely destroyed, and some areas of normal tissue. In these cases the normal tissue is much less than the degenerated areas, while in ordinary eclampsia it is much greater. Indeed, the difference between the lesions seems to be one of degree rather than one of kind, in spite of the marked decrease in the size of the liver in acute atrophy and its slight increase in ordinary cases of eclampsia.

The kidneys in eclampsia are almost always, though not invariably, diseased, but the changes vary greatly in degree and are mostly degenerative, as in an acute infection. Some cases seem to be due to a true nephritis, which was probably present before conception, and should therefore hardly be classed as true puerperal eclampsia. The kidneys in acute atrophy show similar degenerative changes. In both the amount of urea excreted is diminished and in both albumin and casts are usually found in the urine. In our case the kidneys were apparently on the road to recovery when the liver succumbed.

Similar changes (hemorrhages, edema, thrombosis, etc.) have been found in the brain in both eclampsia and acute atrophy, but these lesions are by no means typical of either. Jaundice and hemorrhages into various organs are typical of acute atrophy, but are said to occur only in the most serious cases of eclampsia, cases in which the two troubles are hard to distinguish.

The morbid anatomy of the two troubles is thus very similar; indeed, we can find no clear division between them, though the lesions in acute atrophy are more severe, especially in regard to the liver.

The etiology of both puerperal eclampsia and acute atrophy of the liver is obscure, but both are now generally attributed to a toxemia of uncertain origin; while pregnancy, always a predisposing cause of one, is given as one of the most common predisposing causes of the other. Thus Thierfelder found among 83 cases of acute atrophy 30 in pregnant women, while Quinke says that one-third to one-half of the women with acute atrophy are pregnant.

As just stated, eclampsia is now generally conceded to be caused by a toxemia, produced by faulty metabolism and elimination of waste products from the mother and fetus. This toxemia produces the liver and kidney changes, which, though at first sight variable, seem to be but different stages of the same trouble. During pregnancy the mother is called upon to get rid of toxic matters produced in her own body and in that of the child. The liver, which has the task of converting these bodies into less harmful substances, and the kidneys, which must excrete them, have double work thrown upon them, but as a rule they are perfectly capable of doing this

extra work. At times, however, they give way under the strain, either on account of inherent weakness, or from an increase of toxins beyond their capacity. Thus when the toxins are increased by obstinate constipation, the liver may be unequal to this unusual amount of work, and we begin to get the nervous symptoms (headache, nausea, etc.), due directly to the poisons which have leaked through the liver. In most cases, when the excess of decomposing matter has been removed by free evacuation of the bowels, the liver is again able to take care of the rest of the toxins. In a severer grade of intoxication the liver tissue is injured and its function of reducing waste nitrogenous matter to urea is interfered with, and we get a decreased formation of urea with a further increase in the blood of toxic matters, which the kidneys are called upon to eliminate. The kidneys may succeed in this, or they in turn may be injured, with a resultant further retention of toxins.

Another set of organs, the nervous system, must now be considered, for upon its irritation by the toxins depend most of the symptoms of eclampsia. If the nervous system is strong and not easily irritated, a relatively large amount of toxins may circulate in the blood without producing symptoms. Indeed, cases have been reported as dying without convulsions, in which the organs at autopsy showed lesions regarded as typical of eclampsia (Schmorl). Besides it is stated that women who do not desire children, and especially high-strung women with illegitimate children, are most prone to eclampsia, our case being one of the latter. Whether a depressed nervous condition in turn favors a toxemia with its resulting changes is hard to determine, though it is more than possible.

Acute atrophy of the liver is also generally attributed to a similar toxemia, but is not of necessity associated with pregnancy, in which it may occur either with or without eclampsia, the latter being probably dependent on the irritability of the nervous system. On the other hand, convulsions may occur in cases of acute atrophy in men.

From the foregoing comparison we see that both eclampsia and acute atrophy of the liver are due to a toxemia, which probably produces the variable symptoms and morbid changes on account of the relatively different resisting powers of the organs. Thus the eclamptic symptoms predominate, when on account of inherent weakness the nervous system is relatively most injured, while acute atrophy occurs when the liver is not strong enough to dispose of the toxins, which gardually destroy it, if the patient does not in the meantime succumb to the eclampsia. We may, therefore, divide such cases into three stages: (1) toxemia, (2) eclampsia, (3) acute atrophy of the liver, though the patient usually recovers or dies before this last stage is reached.

(1) A toxemia is always the primary condition, but it may be severe enough only to produce the early symptoms—headache, lassitude, disturbances of vision, and a diminished excretion of urine and urea, with possible edema and albuminuria. In a few cases this stage has been followed by coma and death, without convulsions, the pathological findings being the same as in eclampsia.

(2) In eclampsia (the second stage) the toxemia has become severe enough to interfere greatly with the functions of the liver and kidneys, and to produce the nervous irritation, made evident by the convulsions and coma. The severer poisoning here produces grave lesions in various organs, and often causes death.

(3) In acute atrophy of the liver the changes have progressed still further and have practically destroyed this organ. We have added to the convulsions (which, however, do not necessarily occur) a deepening coma, an increasing jaundice, vomiting, and often purgings of blood followed practically always by death. Here, as in our case, the urinary secretion may increase, but on account of the practical destruction of the liver the patient will nevertheless succumb.

64 Granby Street.

SELECTIVE ABSORPTION BY THE CELL.*

By WILLIAM F. WAUGH, A.M. M.D.,
CHICAGO.
EMERITUS PROFESSOR OF PRACTICE, ILLINOIS MEDICAL COLLEGE.

The blood-vessels and collateral channels of the circulation carry to every part of the human body, to every cell of the countless number that make up our frame, one common nutritive fluid. From this each cell takes up that which it needs, letting the rest pass by. But what does it need? If the cell is exactly equilibrated, if it stands in need of nothing, it takes up nothing. But if any element for which the cell has use is present in it in less than normal quantity, the cell takes up enough of that element to restore physiological equilibrium.

There is a selective power displayed here, for the cells each take up substances differing according as their respective functions and constitutions differ. Accordingly we find the nerve-cell taking up phosphorus, the bone-cell lime, the muscle-cell iron, etc. One cell takes a substance for which it has need, passing by other substances which other cells need and take. Is each cell a distinct, conscious entity, and is the selection a voluntary one? Or is the whole process governed by a wonderful system of complex, interdependent automatisms? There is here an enticing field for conjecture and card-house building, unrestrained by the trammels of real knowledge—the fancy may have full sway.

The substances thus absorbed from the circulating fluids by the cells are usually denominated foods. Foods may be defined as those substances required by the cells to support their structure and sustain their function. The need may be for a molecule of fat, sugar, albumin, salt, acid, water, lime, soda, iodine, phosphorus, etc.

But the need is not necessarily for material always. It may be that there is a defect in the tonicity of the cell, and the need is supplied by a molecule of strychnine; and in that case the cell takes up the latter exactly as it did the other substances for which a need was experienced. Or, the need may be such as is met by a molecule of aconitine, or veratrine, or digitalin—the cell absorbs what will satisfy its needs as felt at the moment.

But these are medicines! I would like to have a definition of foods and one of medicines that would distinguish these. There is evidently no hard-and-fast line between them—is there any line at all? Is iron a food or a medicine? Lime? Manganese? Acetic acid? Phosphorus? Iodine? Potash?

It has been suggested that a food is a substance the need for which is constant, while a medicine is needed only occasionally to fulfil a temporary want. The writer, like some others, has a decided craving for a meal of sauerkraut about once in a winter; but would not care for it three days in succession (it is always best on the second day, you know). The man who attempts to eat a quail a day for forty days soon finds that his need for quail is only occasional, not constant. Sauerkraut and quail, therefore, are not foods, but medicines! There is no definition that establishes an essential, or other than a scholastic, difference between foods and medicines.

We have seen that each cell takes what it needs,

*Read before the Chicago Academy of Medicine, November 17, 1905.

and leaves what other cells need and take. What is there impossible, then, in supposing that when we place several medicines, apparently antagonistic in their action, together in the circulation, each cell may take the drug it requires to restore physiological equilibrium, leaving the antagonistic agent unabsorbed, for the cell that needs the latter? To deny the possibility of this would be to erect a dividing wall between foods and medicines, which we have been unable to separate.

We speak of antagonistic drugs, but in truth it is a question if there is a really and absolutely antagonistic couple in the materia medica. One drug may excite and another restrain a secretion, like the sweat; but it will be found that one stimulates the sudoriparous glands, while the other restrains the flow of blood to the skin, or acts on some other structure to check the flow.

The importance of this discussion lies in the fact that when we come to study the phenomena of disease, we find antagonistic conditions present in different parts of the body. Take, as the most apt example, the oft-quoted case of hyperemia: The presence of an oversupply of blood in the capillaries of any part signifies a loss of the normal tone of its vessels, which admits the surplus blood by distending. This constitutes a vasomotor paresis. But as there is no reason to suppose that the entire quantity of blood in the body has been increased, this oversupply here must be compensated by an undersupply elsewhere; in other words, there are other vessels not normally full, their lumen is diminished, their walls are therefore abnormally strong as compared with their contents, the balance between the centrifugal and centripetal pressures is lost; they are spastic—vasomotor spasm is present.

Strongly favoring this view is the fact that it fully and for the first time explains the good results following the application of diametrically opposite principles in the treatment of hyperemic maladies. How else can we explain the excellent results obtained in pneumonia by those who use the vasomotor constrictors, strychnine, digitalis, and ergot, in maximal dosage; and the equally favorable results reported by equally credible witnesses from veratrum, venesection, antimony, and aconite? Especially as either of these therapeutists succeeds far better than the middle course people, who do neither, but rely on rest and non-interference? According to this view the one who relaxes the spastic vessels and allows the blood to flow out of the hyperemic tract, and the one who contracts the paretic capillaries and forces the superfluous blood out, equally meet the indication and afford relief.

Burggræve went a step further, and recommended that both principles be applied at once, taking the view above suggested, that the paretic cells could take up a tonic like digitalin or strychnine, and the spastic cells a relaxant like aconitine or veratrine, at one and the same time. If this be correct, it is evident that we have here a more effective method of treating hyperemias than either principle affords as applied singly.

The *a priori* reasoning leading up to this conclusion is faultless—it remains to apply the supreme test of clinical trial. There is a mass of evidence on the affirmative side, and little if any on the negative. But it is fortunately a case in which every physician may himself be judge and jury; where no one of us need take any other man's dictum, for we may one and all put the theory to the test of practical clinical application.

Give together aconitine to relax spasm, and digitalin to contract atony; adding strychnine when the vital depression predominates, or veratrine when the excitement of the circulation and respiration passes the desirable limits and the elimination is notably defective; changing from one to the other of these adjuvants as the symptoms indicate, but clinging to the two first named. Give each to produce the desired effect, not by the rigid dosage of the books. Treat the patient, and meet the conditions presenting, instead of giving a set formula for the name of the malady.

For the convenience of those unfamiliar with the agents and methods here advised, the following suggestions are added: Of amorphous aconitine, give half a milligram every ten to sixty minutes to an adult, until the fall of the fever or of the pulse-rate or the evidences of breaking up of the fever indicate a sufficiency of the remedy; then give less frequently so as to sustain the desired effect. Of Germanic digitalin so-called—really digitalein—give a milligram every half hour till the heart is regulated, its rhythm is uniform and the hyperemic vessels are restored to normal tone, as well as may be ascertained with our present means of observation; then regulate the dosage to the needs as with aconitine.

When the evidences of vital depression are manifest, as in asthenic pneumonias, add strychnine arsenate, half a milligram, every ten to sixty minutes until the desired evidences of restored tone and reaction are manifest; then as before, regulate the succeeding doses according to the needs. When the heart is tumultuous and the eliminants are clogged, as in sthenic pneumonias especially, add to the basal aconitine and digitalin the powerful and safe veratrine, half a milligram every half to one hour—much oftener in eclampsia—until the softer pulse, or slight nausea, or laxation evidences the full desirable action; then as before, give it less frequently. It is quite possible that we one day find veratrine indicated, and the next day find depression so predominating that we change to strychnine, and next day, perhaps, go back to veratrine.

The application of such a system demands of the physician a close and discriminating study of the phenomena developing in every case. There is no prescribing *en masse*, no stretching every patient on a procrustean therapeutical bed. Is such a necessity really to be regarded as an objection?

Take the phenomena presented during a chill: The blood is forced out of the cutaneous capillaries by an intense vasomotor spasm, and collects in the internal vessels where there is a dilatation exactly compensating the peripheral contraction. We may attack this condition therapeutically at either end, by relaxants directed against the cutaneous vasomotor spasm, or by contracting agents applied to the relaxing internal vessels. But, whichever we select, why is it that the relaxants do not go to increase the internal relaxation instead of to the cutaneous spasm? Or if we use tensors, why do they not increase cutaneous vasomotor tension instead of acting on the areas of vascular relaxation? Were there no cellular selective discrimination in such cases all active therapeutic intervention in any case of disturbed circulatory equilibrium would be impossible.

What bearing would the admission of this selective action have upon the question of the status of the cell? Is the cell an independent, conscious entity, governed by its own volition, or is its function wholly directed by chemotaxis?

Let us begin with the ameba, as it is found floating free in water. Transfer it to the slide of the microscope, and we see it move, extrude its pseudopoda, etc.—an independent, complete being, its life processes and reproduction exerted by itself as a separate being and not as a part of or dependent on any other animal. There is no place at which a line can be drawn, separating these unicellular creatures governed by conscious volition from those which are

presumed to be not so governed, which dividing line is natural and evident, not arbitrary. Place beside the ameba on a microscope slide a white blood cell, and see if the two can be distinguished. What can be said of the one that cannot apply equally to the other? They are indistinguishable in every respect.

If we cannot draw our line between the ameba and the leucocyte, still less can we draw it between the latter when floating free in the water on the microscope slide and when floating in the blood serum. Change of environment does not constitute a reason for transfer from one primary class to another. For the same reason we find it difficult to make the dividing line between the leucocyte and the same cell when it has assumed a stationary position as part of an endothelial wall; nor between that and the epithelial cell; nor that and the other cells of the body.

The hypothesis of chemotaxis seems to be generally accepted as the preferable working formula for describing phenomena of cell action, but rather from an unwillingness to admit the alternative hypothesis of independent cell volition than from any special testimony in its favor. Of the two the latter seems to be at least the most convenient, since we find writers constantly employing its language in describing the conditions presenting. And this is the more significant in that the impersonation is usually done unconsciously.

In this connection permit me to quote an account given by Major Ross of a three-hour observation of a free flagellum in a blood preparation under the microscope: "At first it wriggled about so for twenty minutes that I could hardly follow it. Then it brought up against a phagocyte and remained there so long that I thought the phagocyte had seized it. Not so; it was neither killed nor sucked in, but was actively engaged in attacking the phagocyte. The flagellum kept at this for a quarter of an hour, and then wriggled away in the direction of another phagocyte. Into this second phagocyte it pushed in several places with one of its ends, and the phagocyte seemed to rear up and try in vain to get around and envelop the flagellum. At last the phagocyte seemed to give up the struggle and flattened itself against an air bubble, the flagellum still attacking it. After fifty minutes and when the flagellum seemed to be getting exhausted, a very curious thing happened. A third phagocyte approached, coming rapidly across the field, but it had no sooner got near than the flagellum left its fallen foe and attacked the new one, holding on to it like a snake on a dog. In one minute the third phagocyte turned sharply around and made off; it went across a whole field, the flagellum holding on to it. This continued for five minutes, after which the flagellum left the phagocyte. By this time the flagellum had become more visible, its movements became gradually slower until, at the end of three hours, it finally curled up and ceased to move."

A Special Form of Adenitis in Appendicitis.—N. Berardinone describes a mono-glandular adenitis in the inguinal regio, above Poupart's ligament and near the external abdominal ring as characteristic of appendicitis. This is not to be confounded with the internal adenitis in the meso-appendix, ileocecal angle, and along the mesentery. Out of six cases observed by him this form of adenitis was present in five, all moles. It is to be felt on the second day of the disease and increases rapidly in size, being about the size of a small cherry. The gland gives a sensation of painful tension that is quite bearable. It is more enlarged when the glandular swelling returns. The subserous lymphatics of the cecum anastomose with the rete of the parietal peritoneum, and by this path the lymphatics of the cecum and appendix communicate with different glands. The swollen gland represents an inflammatory process of a certain amount of virulence, and is an important diagnostic sign in appendicitis.—*La Riforma Medica*

EYES AND EARS THAT MIGHT BE SAVED.

AN APPEAL TO THE GENERAL PRACTITIONER.

By SAMUEL S. WALLIAN, A.M., M.D.,

NEW YORK.

No human calamity can exceed in gravity the loss of the two most useful and necessary of the special senses, sight and hearing. Atrophy of the optic nerve, from whatever cause, is conceded to belong to the *opprobria medicinæ*. As usually observed, it is progressive and results sooner or later in total blindness. Loss of the sense of hearing is sometimes associated with it or follows in its wake. The causes of optic atrophy are varied and dissimilar. A majority of specialists and general practitioners have so often traced it to specific causes that they incline to look with suspicion on every case that presents. This opinion is unquestionably too sweeping and pessimistic. Cases arise from septicemia, from hemorrhages in the vicinity of the optic tract, from benign or malignant neoplasms, from circumscribed paralysis, and from sudden shock to the nervous system. Following some serious accident, mental explosion, or psychic shock, subjects have been known to retire with apparently unimpaired vision to awake next morning totally blind. Cerebrospinal meningitis and albuminuric retinitis are accredited as frequent causes. In many cases the cause cannot be positively or satisfactorily traced. When paralysis is the alleged cause other of the special senses are apt to be involved, as the hearing, taste, or smell, one or all of them.

Arising from such a variety of causes it is not surprising that no two cases are found to exactly correspond in their characteristics. Sometimes but one eye is at first affected, although its fellow is almost certain to share in the degenerate process without much delay. In a majority of cases the two eyes are not equally or simultaneously involved. One observer asserts that the left eye is more frequently the more seriously affected and first to fail.

The prime object of this paper is to make an earnest appeal to the general practitioner to make a renewed and much more thorough study of these unfortunate and distressing cases, which are apparently becoming more and more frequent in every community, with a view to saving thousands of pairs of eyes—often pathetic and unquestionably innocent eyes—and other thousands of ears, that are now permitted to drift slowly into the realms of hopeless night and perpetual silence.

These cases have been universally looked upon as belonging to the oculist, aurist, or neurologist. If considered in the light of the pathological conditions existing they rationally come within the purview of the general practitioner. Lest this claim may seem presumptuous, what are the pathological disturbances involved?

Whatever the primary cause of atrophy of the optic or any other nerve, the essential resultant of that cause is starvation of the nerve. This may arise from any accident or process that causes pressure upon the nerve or upon the circulatory vessels supplying it with nutrition. Nerve-degeneration may result from a general depravation or "run-down" condition of the system, but this is rarely the cause of either blindness or deafness. The more usual causes are exudations of plastic material, hemorrhages, or morbid growths, following inflammatory action in the vicinity of the nerve. When the circulation of any organ or part is either impeded or cut off the part fails of its normal supply of nourishment, and atrophy is the inevitable result.

Of all the nerves of the body the optic nerve is

perhaps one of the most peculiar and unique. Its immediate origin is the optic commissure, in which body the nerves of each side partially decussate, their remote origin being in the optic tract, the fibers of which latter are chiefly derived from the optic thalamus.

The optic nerve is second in the order of its exit from the cranium, and second also in the list of nerves of special sense. It receives some fibers from both the tuber cinerium and the lamina cineria. Its blood supply is derived from the internal carotid, through the ophthalmic artery, which latter is quite tortuous, giving off numerous small branches which are even more devious and indirect in their course. This tortuosity, coupled with the small caliber of these vessels, may be a principal reason why a very small tumor or slight exudation in this locality presses disastrously upon the nerve and interrupts its nutrition. This condition, if not quickly relieved, eventuates in progressive atrophy of the nerve, as already stated. The condition is often described as paralysis of the nerve, but as the paralysis is the result of the pressure it is obvious that the latter is the underlying cause of both paralysis and atrophy.

As a matter of course the oculists and specialists take cognizance of the causative factors and make strenuous efforts to bring about resorption of effused products or abnormal growths, for the most part by heroic doses or persistent use of mercury and the iodides; but if any considerable number of cures have ever been accomplished by this method they certainly are not recorded. Nevertheless most practitioners feel in duty bound to follow precedent and prescribe this treatment as a forlorn hope, and as the only resource thoroughly endorsed by theory and tradition. When at last this treatment has proved utterly futile and the stomach resolutely rebels against any more of the remedy, it has latterly become the fashion to prescribe even more heroic and gradually increasing doses of strychnine, in the vague and hesitant hope that the special nerve or nerves involved may at least partially and temporarily respond to this powerful and more or less dangerous nerve prod. Although some patients have persuaded themselves that the use of this drug, pushed to the extreme limit of tolerance, has for a time enabled them to "hold their own," if there is an undoubted case on record of actual cure of either blindness or deafness from the use of strychnine, pushed even to the dosage of one grain per diem, I have failed to find it.

To make good the argument that patients suffering from atrophy of the optic nerve or loss of the special senses should be referred to the general practitioner, competent testimony is found in the fact that these subjects are, with few exceptions, the victims of some form of dyscrasia. This may be from accident, from constitutional or specific infection, or from one or more bad hygienic habits. A majority of them are badly nourished. This does not imply that they are underfed,—more of them are overfed, and as a rule all of them are injudiciously fed. As a result they are in a state of morbid metabolism. For this reason the general practitioner is the man who is most thoroughly prepared to take these cases under his immediate observation. It is he who can temporarily ignore the local trouble and investigate the general and special condition of his patient's entire organism. He will begin by peremptorily interdicting all further use of mydriatics, since patients suffering from progressive atrophy of the optic nerve invariably insist that each successive induction of mydriasis aggravates the trouble and causes further and more rapid loss of vision. Having accepted the diagnosis of atrophy, further use of the ophthalmoscope can do no more than to satisfy a very natural curiosity to watch the progress of the case by means of periodic inspections. The oculist may impatiently flout the idea of doing any harm in this way, but the general practitioner will insist upon his injunction as a matter of possible prophylaxis. The next step will be to inquire into the hygienic habits of omission and commission on the part of his subject. A majority will be found to be bad feeders, consuming too much starch and too little refuse, too much nitrogenous food and too little oxygen. A rigidly correct dietary will restore a condition of normal instead of the morbid metabolism that has become a habit. Instead of permitting foods that clog the system without thoroughly nourishing it, that overtax the various emunctories and eliminative organs, thereby inducing the deposition of unused material, and fostering the formation of adventitious tissue in various parts of the organism, this latter tendency must be strenuously and persistently combated. This makes the question of diet fundamental to all other measures, and any merely perfunctory or compromising adjustment of it will seriously interfere with all other curative efforts. In many cases it will be found that the food ingested can be decidedly diminished in quantity at the same time that its quality and therefore its sustaining energy is actually increased. To this end the proteid element must be definitely adjusted. In other words it must be supplied in sufficient proportion adequately to meet the actual needs of the organism without contributing a single calorie in excess of such current needs. In plethoric subjects, on the contrary, it will be quite necessary to reduce it temporarily below the normal quota, in order to favor absorption of the adventitious products of former excessive indulgence. The diet must be further restricted in the matter of starches, sweets, and concentrated foods. The modern tendency is toward an excessive consumption of carbohydrates. In fact this tendency has become so universally established as a national habit that the "prepared" and "predigested" food venders are no longer content to cater to invalids who have lost the power to prepare and digest their own food, but are loudly advocating their multinomial products, of which nonproteid starch is the invariable basis for general consumption. In the face of the only spasmodic and passive protests of the medical profession the almost universal adoption of these ready-to-eat and temptingly elegant dishes has become a menace to the future of the race. Mastication is becoming a lost art, and the race is early toothless, chiefly from disuse of the teeth. The prevailing and increasing habit of indigestion comes from the passive inertia of digestive organs that lack their normal and necessary stimulus. In fact, mastication is now accomplished by the machinery of the mills, and the balance of the digestive act is largely performed in the laboratories of the food venders. To counteract the resulting conditions the demand for salines, laxatives, and cathartics is incredibly large and steadily increasing. Aperient and cathartic spring waters and their numberless imitations and sophistications are constantly consumed, at the rate of millions of gallons daily, and the price of aloes, cascara, and the other stimulators of peristalsis is as standard as that of sugar or flour.

The dietary prescribed for these patients must be rich in phosphates and nerve-nourishing elements. But it is useless to depend upon the preparations of the hypophosphites, since the assimilation of inorganic mineral matters is inadequately if at all realized. The true and only reliable source of assimilable phosphates is to be sought in the phosphorus-bearing foods, of which two illustrative examples are entire

wheat and yolk of eggs. Other grains and many of the vegetables used as food yield appreciable quantities of iron, the phosphates, and other needed mineral elements.

Finally, the question of refuse in the food is one which is too generally overlooked by physiologists and dietists, and from mere whim and fashionable prejudice, wilfully rejected by invalids to whom it is of the utmost importance. The husk of the grains, especially that of wheat, not only contains some of the rarer and most essential nutritive properties of the grain, but also constitutes nature's normal, unobjectionable, and effective stimulus to digestion, assimilation, and peristalsis. Hence these fibrous and cellular structures contribute both directly and indirectly toward perfect nutrition of all the tissues of the body. They do this in the first place by compelling more perfect mastication of all the food ingested, secondly, by contributing the rare elements stored in them, and thirdly, by their stimulating action upon the muscular coating of the alimentary tract. The importance of these several offices can hardly be overestimated.

After having corrected as far as possible these dietetic habits of omission and commission, no measure more directly or more rationally promotes resorption of effused products in any part of the body than habitual and persistent free water-drinking,—not merely a few extra glasses, but several quarts per diem. For this purpose distilled water is greatly to be preferred, the contained mineral salts of "hard" water being decidedly objectionable. The water is to be imbibed between meals and not at table.

All these measures and precautions will be effectively seconded by a weekly or semi-weekly resort to the Turkish bath, substituting when feasible the electric cabinet for the ordinary hot room. Many modern bath establishments have installed this electric appliance, and it has marked advantages over the old hot room, where the ventilation is usually so poorly accomplished that the patient is compelled to rebreathe his own and his neighbor's emanations while taking his "sweat." In the electrical cabinet the head remains outside, and the time required to induce profuse diaphoresis is less than one-half that required in the dry air of the hot room. Much is also claimed as to the penetrating and stimulating effects of the light rays.

The foregoing outlines a hygienic background on which to erect a promising therepeutic effort. Indifference or inefficiency in regard to any one of the mentioned items will much retard or entirely negative all the other means invoked.

It is hardly necessary to state that the use of alcoholics and narcotics of every kind must be strictly prohibited.

As to drug aids in the promotion of absorption, the pharmacopeia offers little that is reliable. In persons of full habit, brisk purgation, at the outset, may sometimes seem desirable. The iodides hold out most promise, yet their internal exhibition is generally disappointing. External applications and cataphoresis may be employed with more assurance. The latter must be used with the utmost circumspection, and by means of reliable and accurately controllable apparatus. A hygroscopic cataplasm composed of a suitable earth-base, made plastic with glycerin, and containing five or ten per cent. of iodide of ammonium, applied to the temples and repeated every night, is probably one of the best external auxiliaries.

Thus far the onus of effort has been toward influencing resolution of recent or old adhesions or semiorganized exudations of plastic material. If this effort is attended with some degree of success it then remains to rouse the dormant, debilitated, and shrunken nerve to its proper function. With the improved means now at the command of the general practioner, this is not a hopeless undertaking. The two active measures available are the high-frequency current, properly modified and adapted, as illustrated in the violet ray and the D'Arsonval modality, and mechanical vibration. Great progress has been made in the matter of improved appliances for exhibiting these rational and physiological agencies for the restoration of disordered, debilitated, or obstructed functions. One of the latest applicators is called an autocondenser. It consists of a hinged and interarmored chair attachment, by means of which the spinal region, and through it the entire system, is quietly suffused with the D'Arsonval high-frequency current. It is an efficient stimulator of the sympathetic system and corrector of the general metabolism of the body, and is being used with marked success in various degenerative conditions, especially in the more serious forms of anemia, and even in diabetes. Its forte seems to be to arouse the hematopoietic function to a high degree of efficiency. To do this it must necessarily agument secretion, assimilation, absorption, and elimination, since all these processes are inter-related and interdependent. It thus promotes both constructive and destructive metamorphosis, which is the paramount object in all our battles with chronic disease of whatever nature. All morbid growths, adhesions, infiltrations, and semiorganized exudates consist of dengenerate tissue, and the electric modality known as the violet ray has certainly demonstrated its efficiency in breaking down morbid, adventitious, and degenerate tissue, whether classed as benign or malignant. It accomplishes this result partly by relieving the vital forces of obstructing material, through the emunctories, and partly by imparting fresh impetus and nutrition to overworked or starved nerves.

Vibratory motion as a therapeutic resource is not specially new, since it was employed a generation back, by Vigoroux, in Paris; but its earlier history has been practically forgotten, probably because the means employed in its application were so crude and inconvenient, and its original field was so very limited. It was tried merely in a few cases of functional nerve disturbances, and it was not dreamed that it could be made an effective agent in a wide variety of chronic conditions not associated with disordered nerves. It is not yet appreciated at its intrinsic value, even by many of those who are casually, carelessly, or tentatively using it. It is however, slowly establishing its claims as a strictly physiological and rational means of accomplishing results that have hitherto been out of reach or attained with great difficulty by other measures.

But the physician who invokes its aid and then uses it in a routine and perfunctory way, without knowing what physiological changes it is competent to produce, why it produces these changes, or how to apply it so as to bring about these changes, will fail in as many cases as he will succeed, and will understand neither his failures nor his successes.

In all these cases of defection of the special senses much, in fact invaluable, aid can be realized by a judicious use of mechanical vibration. In the effort to restore a more or less normal degree of function to the involved nerves no known means promises so much as this. Of all the means available this merits the name of dominant. Most of the others are either preparatory or contributory and auxiliary. Yet nothing of the slightest value is to be neglected, since it is the combination that will give success, if success is to be attained.

Based on a number of quite uniformly favorable reports from abroad and from a few observers in this country, I have recently employed radioactivity

in a limited number of cases of atrophy of the optic nerve with apparently good results. As this remedy was used with the other means mentioned it is impossible to determine what proportion of the results should be ascribed to it. It certainly merits a thorough trial in all cases of tissue degeneracy.

509 Fifth Avenue.

NAILING THE HEAD OF THE HUMERUS FOR FRACTURE OF THE SURGICAL NECK, WITH REPORT OF A CASE.

By H. A. HAUBOLD, M.D.,

NEW YORK.

CLINICAL PROFESSOR OF SURGERY, NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE, SURGEON TO HARLEM HOSPITAL.

Fracture of the surgical neck of the humerus has always been a difficult condition to treat with a favorable outcome. To those engaged in hospital practice it is a not infrequent occurrence to meet with cases of faliure of union or union with faulty position and consequent loss of function. It is true that this kind of fracture occurs without displacement, or with such as can be readily overcome by manipulation and apparatus; but, unfortunately, this is the exception, and the rule presents us with cases

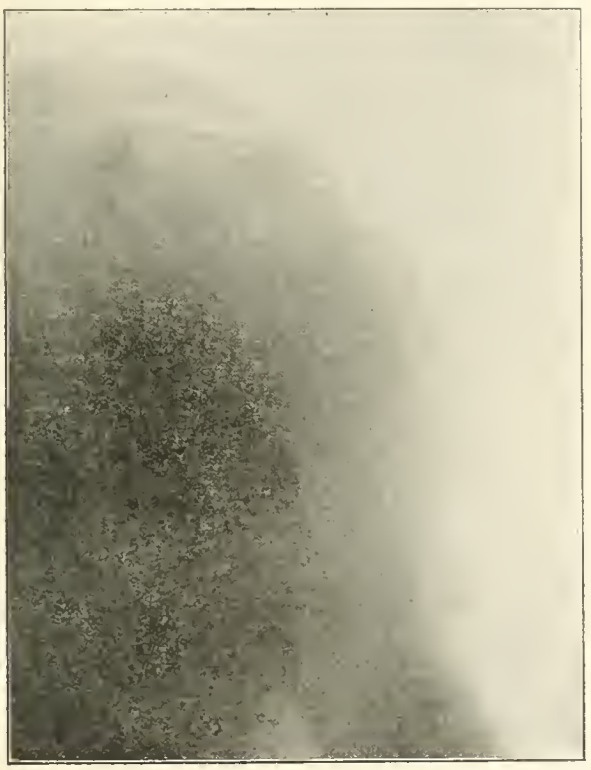

Fig. 1.

Fig. 2.

with marked displacement and one which cannot be overcome by the means mentioned.

The lesion occurs at the junction of the cancellous and spongy bone, that is, between the tuberosity and the insertion of the pectoralis major; usually as the result of violence directed toward the median line, such as a fall on the shoulder.

The lower fragment is drawn inward by the pectoralis major and latissimus dorsi, and pulled upward by the deltoid; these are powerful muscles and hold the bone quite firmly in its malposition, at times forcing it against the coracoid process. The proximity of the large vessels and nerves renders them liable to injury by the jagged edge of the shaft, so that interference with motion and sensation of the hand and forearm may occur.

The upper fragment is abducted and in the cases of marked displacement the fractured surface points directly outward at right angles to the glenoid cavity; this is due in part to contraction of the supraspinatus, infraspinatus, and teres minor muscles, and partly by pressure from below of the upper end of the lower fragment.

It is to this class of cases that the one herewith reported belongs:

J. T., age 46 years, a bookkeeper, on March 4, 1905, fell with much violence, being a large, heavy man, striking on the left shoulder. Soon after the injury the shoulder became much swollen and exceedingly tender, consequently difficult to examine. The patient came under my care two days later, through the courtesy of Dr. J. H. Guntzer. Examination showed a much swollen shoulder, with extensive ecchymosis reaching from the clavicle along the sternum to the free borders of the ribs and down to the fingers; there was tingling in the fingers in the area supplied by the median nerve. Dugas' test was negative. The elbow was abducted and could not be brought in contact with the side of the thorax. Manipulation showed that the head of the bone was in the glenoid cavity, but that it did not rotate with the shaft of the bone. The radiograph speaks for itself (Fig. 1). Crepitus was present only when pressure was made on the elbow, forcing the lower fragment against the side of the upper one.

The methods of procedure employed for the relief of this condition are many, but may be divided into those which confine the patient to bed with suitable traction apparatus, the ambulant methods, and the operative endeavor. The ambulant methods may be dismissed with the statement that they are applicable only to those cases in which correction of the displacement can be accomplished by manipulation. The recumbent position with extension is a most serviceable mode of treatment and is strongly recommended by many surgeons, but does not always overcome the deformity, and vicious union is a not infrequent outcome.

The operative treatment, at least in this case, gave an exceedingly favorable result, warranting the belief that in cases of marked displacement, not readily overcome, further trial is justified. Of course each case must be attacked on its own merits, and the degree and character of displacement should be carefully studied, to which end the radiograph is an invaluable aid.

In the case under consideration, it was quite impossible to overcome the displacement, a fact readily understood from a study of the accompanying radiograph. Operative interference was decided on, and the following procedure executed: Under chloroform narcosis, Langenbeck's anterior incision was made, the deltoid separated from the pectoralis major (avoiding the cephalac vein), and the fracture exposed. There had been much subcutaneous hemorrhage and the upper end of the lower fragment was somewhat comminuted; the loose fragments were removed. The periosteum was severely lacerated. The fragments were brought into apposition with considerable difficulty, and only by forcibly prying the lower fragment outward with the aid of a periosteal elevator. With the fragments held in place, a small skin incision was made at the outer edge of the acromion process and a four-inch steel nickel-plated nail driven through the head of the bone and onward into the shaft, thus firmly fixing the fragments in place. When the control of the periosteal elevator was removed, the displacement did not recur. About three-fourths of an inch of the nail, with its head, was permitted to protrude from the skin. Drainage at the posterior aspect of the wound was established, the rubber tube coming out behind, opposite the lower angle of the anterior incision. The anterior wound was closed in the usual manner. The usual protective dressing was supplemented by an axillary pad and a Velpeau bandage. The condition of affairs immediately after operation is well shown in Fig. 2. On the third day the drainage tube was removed and the dressing renewed. At the end of a week a plaster-of-Paris dressing was employed, into which one window was cut at the site of the incision, and a small one at the location of the entrance of the nail, through which it was readily removed four weeks later, without disturbing the plaster cast. At the end of the fifth week the cast was removed and a lighter one applied; at this time union was quite strong and ultimately was complete. The subsequent treatment consisted of passive motion and massage. The injury to the median nerve healed with no paralysis remaining. There is now (eight months later) slight limitation to the motility of the shoulder, although this is not apparent as far as the usefulness of the limb is concerned, being fully compensated for by the movements of scapula.

SUTURES AND THEIR PREPARATION.*

By W. H. WATTERS, M.D.,
BOSTON.
PROFESSOR OF PATHOLOGY, BOSTON UNIVERSITY SCHOOL OF MEDICINE.

A PAPER on a subject such as the present one, "Sutures and Their Preparation," written by one whose time is exclusively devoted to pathology, cannot be expected to cover anything more than the results of laboratory experiments. And as such experiments are often under far different conditions from those obtaining at operation, the results must be accepted only as theoretical. In all theories the experimental results must agree with the clinical tests in order to insure validity. And so here theoretical and practical results must be equally positive and united to demonstrate the value of any method. As my experiments have been largely confined to one kind of suture material, that which I have to say will pertain particularly to that one, although probably applicable to others.

Catgut, a material made from the intestine of the sheep, is capable, when buried in living animal tissues, of soon being absorbed. As such, it has long been valued in the surgical world. A material taken from a place so notoriously rich in bacterial life as the intestine must be most carefully prepared by the most effectual methods of sterilization, prior to its insertion into the human body. Such sterilization, while most simple when dealing with instruments, rubber, silk, etc., becomes more complex when catgut is used. In the former case, the application of boiling water for a time is efficient. With catgut, however, such a method is useless, for while it certainly does kill all microorganisms, it at the same time destroys the usefulness of the material.

Many ways have been devised to obviate this difficulty. A mere rehearsal of such would be of no avail at the present time. Many have certainly been effectual, but are so expensive as to be a severe drain on the resources of even the best hospitals.

My purpose at this time is to give a few notes on the results of a very simple and inexpensive method devised by one of our colleagues. The writer lays no claim to originality in his work or its details, but has merely followed as closely as possible the directions as given by the author of the original article.

This original article, "A Method for Sterilizing Catgut," by W. F. Wesselhoeft, M.D., appeared in the medical literature of 1900. In giving a brief résumé of this, I will quote freely: "The gut is cut into the desired lengths (from 24 to 30 inches commonly). Each strand is wound about two fingers and put into a small paper envelope which is not sealed. Two of these small envelopes, each containing a strand of gut, are put into one slightly larger, two inches square, and this envelope is sealed.

"These envelopes are of strong bond paper, and in their manufacture their angles and seams are accurately closed and gummed. The outer envelope is a little more than two inches long, and is folded on itself to two inches square, thus making what is known as a safety lap closure. The envelopes, filled and sealed, are now put over a radiator or register to be thoroughly dried out. After being dried they are ready to sterilize. The sterilizer is a square brass box, tinned inside and out, with an inside measurement of 2¼ inches on a side. The cover, which is separate, is fitted with a rubber gasket, and is fastened on tight by four steel bolts and thumb-screws. The sterilizer is cast square to fit the envelopes in order to economize the alcohol.

"The envelopes containing the gut are placed in a wire basket made to fit, and so carried into the sterilizer. Absolute alcohol (99 8-10 per cent.) is now poured in up to the point which is marked by the upper end of the basket. The cover is screwed on and the sterilizer is hermetically sealed. The basket is a little less than nine-tenths the length of the sterilizer inside, and the end of the basket marks the point to which the alcohol is poured. Alcohol boils at 172° F., and when heated to 212° it expands a little less than one-tenth of its volume. The sterilizer, filled with the envelopes and with alcohol, is immersed under boiling water and left there for one hour. This raises its contents to 212° and develops a pressure of twenty-five pounds to the square inch, which must squeeze hot alcohol through every fiber of the gut.

*A paper read before the Massachusetts Surgical and Gynecological Society, June, 1905.

"The sterilizer is taken out at the end of the hour and placed in cold water for a few minutes to reduce the temperature and relieve the pressure before opening. It is then opened and the basket containing the envelopes is pulled out. The envelopes are dropped into a towel and again put to dry, which takes fifteen or twenty minutes. The gut is now ready for use. Each strand is sterile; it is in a sterile envelope which is in another envelope, and it can be kept sterile indefinitely and carried about conveniently. When desired for use, an attendant opens the outer envelope and bends back the tongue. With sterilized forceps the operator or his assistant takes out the inner envelopes, which, with the gut they contain, are absolutely sterile."

Such a process is relatively simple, and less than one-fifth the cost of the catgut as ordinarily prepared. Now comes the crucial question—is it effectual and sure? Does it certainly kill those terrible structures of which we hear so much—spores? Even granting for the moment that no experiments have been performed to determine this point, how many cases have occurred in our hospital during the last five years that have been caused by sporiferous bacteria? So far as the writer is aware, after having watched the use of catgut thus prepared in thousands of cases, not one such has occurred. The principal criticism that has been brought against this method is that it does not provide for fractional or intermittent sterilization.

Let us digress for a minute to look carefully at this question of fractional sterilization. What is it? When is it useful? When is it of no use? Certain bacteria, when subjected to unfavorable environment, possess the power of forming within their own bodies structures capable of resisting those conditions that are fatal to themselves. These structures are called spores. They have a thick, dense outer covering that enables them successfully to withstand drying, great heat, and lack of nourishment. They can even live for a few minutes in boiling water. When their surroundings become more favorable, this outer wall ruptures and a new bacillus emerges, similar in all respects to the one that formerly produced the spore. These spores are supposed to exist almost everywhere, and in laboratory media are killed in the following way: A given culture medium is subjected to moist heat at 100° C. for twenty minutes. This kills all the bacteria present, but will not positively kill all the spores. The flask is then set aside for a day in a warm place, thus giving the spores a chance to develop under favorable surroundings into mature bacteria. It is then sterilized a second time to kill those bacilli which have developed in this manner. This is again repeated the third day, so that any remaining spores may also develop and then be killed. Remember that the bacilli produce spores only when the environment is unfavorable, and these spores in turn produce bacilli only when the surroundings are favorable for their growth.

Now let us see what takes place in the fractional sterilization of catgut. It is subjected to a temperature of 100° C. for fifteen or twenty minutes, and then allowed to stand till the next day. It is claimed that the spores that may be present will produce bacilli just as they did in the culture media. But such is not the case. The sutures are either dry or they are immersed in some liquid that possesses no nutriment. Therefore conditions favorable for further development are not present and the spores retain their same condition with the same resistance. And so sterilization on the second day will be no more effectual than it was on the first, and the process may be continued indefinitely without result. Fractional sterilization, then, under these conditions is not effectual.

In comparison with this let us see what results are attained by a single long sterilization in a mild antiseptic and under pressure, according to the method above described. Many experiments have been made during the past five years with catgut prepared in this manner. The writer has repeatedly taken from the operating table many specimens of the different sizes used, and placing the entire strand in liquid culture media watched for days for indication of bacterial life. All such efforts have been in vain—never has he been able to demonstrate that any strand was not sterile. Last winter the head nurse found some envelopes that had been sterilized eighteen months before and stored away in an obscure corner. Examination of twelve strands from these envelopes gave uniformly negative results. Eleven similar envelopes were found lying in a drawer of the pathological laboratory with some rubbish, having been placed there more than a year previous, and often pushed about. Even in this case, seven of the eleven strands were sterile.

The latest series of experiments has been made with the intention of demonstrating that the process does certainly kill different microorganisms and spores. With this aim in view, a number of strands of catgut that had been lying loose in the laboratory for months were allowed to remain for twenty-four hours in a bouillon culture of *Staphylococcus pyogenes aureus*. Others were placed in a similar culture of *Bacillus typhosus*, and still others in cultures containing different varieties of spore-forming bacilli. They were then removed from the medium and allowed to dry partially. After being placed in the double envelopes as already described, they were sterilized according to directions, removed, dried, and placed in sterile culture media. The medium is still as clear as it was prior to the entrance of the strands, and no bacterial life can be found. In other words, we have a demonstration that this method does kill spores. And as spores are the most resistant forms of microorganisms, we may safely conclude that it will also kill all forms of bacteria with which we are acquainted.

RADIUM, ITS KNOWN MEDICAL VALUE.

By MYRON METZENBAUM, B.S., M.D.,

CLEVELAND, O.

From a careful and complete résumé of the medical literature regarding the use and value of radium, and from a fairly large personal clinical experience covering a period of nearly two years, the following inferences can be drawn:

1. That lupus responds promptly to the action of radium and that this result is obtained as readily as with the Finsen light or the *x*-rays, and that these results seem permanent.

2. That small epitheliomata, without glandular involvement, heal rapidly under the action of the radium rays.

The epitheliomata may be situated on the face, within the nasal cavity, mouth, pharynx, larynx, vagina, rectum, or bladder, provided the tubes of radium can be brought into intimate contact or close proximity to the diseased area.

Large epitheliomatous areas of the mucous membranes may not be influenced to any marked degree, probably because in large areas the disease is not only superficial but the deeper tissues are involved as well. Epitheliomata on the skin respond far more readily than those of the mucous membranes; this is probably because the skin is kept dry and is not irri-

tated by moisture or friction of the parts. The healing of epithelioma under the action of the radium rays seems to be permanent.

3. The rodent ulcers about the face and head respond better to the action of radium than to any known agent excepting the *x*-rays, and the results are better than those usually obtained by surgical interference.

4. Deep-seated, malignant growths seem beyond the influence of the radium rays, and even when an incision is made into the growth and the tube of radium is inserted into its interior there is then only a histological change in that part of the growth surrounding the tube of radium, as is demonstrated by a microscopical study of the tissue. Even if the radium rays exerted any beneficial influence on truly malignant, deep-seated growths, the fact could not be used to any great advantage in these cases, for the local action would be so pronounced as to cause an ulceration of the skin before it could influence the growth beneath.

5. In certain cases of total blindness, possibly where some of the fibers of the optic nerve still remain intact, a sensation of light may be noted when a tube of radium of high activity is placed in front of the eye or against the temporal region. But thus far radium has given no beneficial results in the treatment of blindness.

6. When tubes of radium are applied to old scars resulting from healed lupoid ulcers, it causes them to lose their rough and fibrous appearance and renders the area quite smooth and pliable, so it resembles more nearly the healthy tissue.

7. Radium cannot be used like the *x*-ray to obtain skiagraphs, for it requires at least twelve hours' exposure before the rays penetrate the hand, and then there is not as sharp a differentiation between the tissue as is shown by the *x*-rays. Again, from such a long time exposure the skin would be so irritated as to cause it to ulcerate.

8. The beneficial results obtained from radium have been equally good when using tubes of low activity, costing but a few dollars, as when using tubes of very high activity, costing several hundred dollars.

9. Up to the present time, radium is to be classed with the Finsen light, *x*-rays, and surgery, in the treatment of lupus, and with surgery and the *x*-rays in the treatment of rodent ulcer and small epitheliomata.

1220 Wilson Avenue.

The Rôle of Forests and of the Constitution of the Soil in the Development of Disease in France.—René de Gaulejac has made very interesting studies in relation to the effect of forests and the constitution of the soil on the development of bacteria. His attention was called to the subject by the fact that deaths by tuberculosis in the various parts of France were only incompletely explained by the rôle of altitude and climate, as well as by the influence of alcoholism or by crowded populations in the cities. He concludes that the existence of forests is an active element in keeping down bacteria. The qualities of the air of the forests, the functional properties of the trees, and the natural lives led by those sojourning in the woods explain the greater resistance of their organisms to bacillary infection. Our knowledge of the beneficent effect of forests offers an indication for the location of sanatoria in woods of pine trees and fir trees especially. The Swiss have already taken advantage of this knowledge. The rôle played by the soil has less to do with the curative treatment than with the relative resistance which it confers on the organisms living on it. Its beneficent effects depend upon its constitution, upon vegetation which it produces, and upon the water coming from it which is more or less charged with salts useful for the nutrition of human beings.—*La Presse Médicale.*

Nystagmus in Children.—Sydney Stephenson discusses three causes of nystagmus which he declares are collectively commoner in children than all the other causes put together. These are, gyrospasm, partial albinism, and post-meningitic or hydrocephalic influences. The recent onset of the affection which is often unilateral, the peculiarities of the nystagmus—a quivering, rolling, twitching, or "twittering" movement of the eyes—and the age of the child, generally from six to eighteen months, should suggest that this is an instance of "gyrospasm," "head nodding," "spasmus nutans." These children show signs of rickets. These cases are commoner in winter than in other seasons of the year. This fact is considered to be in some way connected with the absence of sunshine. It is doubtful what relation exists between this disease and dentition. These children are often intelligent beyond the average and very good tempered. Sudden noise is apt to startle them. Temporary lapses into unconsciousness may be present. The affection may be present in the other children of the family. The disease always gets well after a few months, with or without treatment. Antipyrin in one-grain doses, two to four times a day, is the best drug to give. Bromides have also been recommended. The writer next calls attention to the light hair and eyelashes, the glowing pupils, the pink iris, the nystagmus, the photophobia, the defective sight of the typical albino. He has recently observed an interesting group of cases in which imperfect sight and nystagmus coincide with much slighter signs of albinism. This condition is apt to run in families and is apt to affect the males. The tendency is transmitted by the females. The essential nature of this condition is often overlooked or misinterpreted. The last type, that of post-meningitic and hydrocephalic nystagmus, offers no special peculiarities. Its nature can usually be recognized from the history of the case.—*The British Journal of Children's Diseases.*

Subacute Cerebral Rheumatism.—Gandy and Bornait-Legueule report an interesting case of this kind. The patient, a young man 21 years old, showed on the ninth day of a third attack of rheumatism of the ordinary acute course, cerebral complications of a delirious nature. Death occurred at the end of eleven hours. At the autopsy many lesions of the serous membranes were found; mitral endocarditis, aortic and tricuspid, adhesive pericarditis, double pleuritis, common congestive lesions of the liver and kidneys, and congestion and bloody suffusion of the cerebral meninges. It is well known that cerebral lesions appear in the serious forms of this disease with multiple visceral localizations. This proved true in the present case, but the reasons generally given for the appearance of cerebral rheumatism—renal and hepatic insufficiency—could not be ascribed as the cause of the cerebral troubles in this case. There was no lesion of these organs sufficient to account for the cerebral disturbances. It seems probable that the renal congestion and cerebral disorders were to be traced to a common cause.—*Journal des Praticiens.*

Pyelonephritis in Pregnancy.—According to Gaussel-Ziegelmann, the prophylaxis of pyelonephritis in pregnancy consists in careful attention to the digestive system, the prevention of constipation, and the avoidance of causes which exaggerate renal susceptibility, such as cold, overfeeding, and so on. If the trouble once declares itself, however, the absolute milk régime should not be prescribed. This is necessary in the acute period, but after that the lacto-vegetarian régime should be instituted, at least when the condition of the kidney is not actually compromised. Rest in bed is indispensable. The use of drugs in this trouble relates to the digestive system and to the urinary system. Purgatives are indicated at first. Antiseptics are used also. Surgical intervention may be indicated in cases in which the life of the patient is in danger.—*Revue Française de Médecine et de Chirurgie.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN. A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 6, 1906.

A DEFENSE OF THE PARASITIC THEORY OF CANCER.

"CARCINOMA is a parasitic disease," was the bold and somewhat dogmatic statement adopted by Mr. H. T. Butlin as the title of his Bradshaw Lecture at the Royal College of Surgeons in London on December 13. He began with a confession of grave disappointment that the Director of the Imperial Cancer Research Fund should have been justified in saying, in his report, that "the parasitic hypothesis has been subjected to severe criticism in practically every textbook of pathology," and especially that the director himself should have joined in this ruthless and almost universal condemnation. Undaunted by this weight of authority, Mr. Butlin maintained stoutly that the carcinoma cell is really an independent organism, like many a protozoan; lives a life wholly independent and proper to itself; lives, too, as a parasite in the body of the animal affected, deriving its nourishment from its host, and doing nothing to repay him for the sustenance of which it robs him. Of the influence of soil and climate he said that one cannot at present say much; the age-incidence is now in the ascendant.

The requirements to be satisfied to show the cell to be an independent organism were given by Mr. Butlin as follows: (1) It should present the same or similar characters in every part of the host in which it is present; (2) it should be transmissible from one part to another part of the same host; (3) it should be transmissible from one host to another under certain conditions; and (4) it should be capable of living outside the body of the host. The first and second of these conditions are fulfilled regularly and frequently. The third condition—transmissibility from one host to another—involves the question of the infective nature of the disease. Mr. Butlin preferred the term communicable to infectious or contagious; for, while contact with a sufferer or breathing the same air might not result in transmission of the disease, the speaker held that there remained no possible doubt that cancer is communicable.

Three points, namely (*a*) the character of the cell, (*b*) the structure of the tumor, and (*c*) the age-incidence, make it difficult to conceive of a parasite introduced from without. It has, in fact, been suggested that the parasite is actually formed within the body of the host, being developed in some way from his elements. But that, Mr. Butlin justly said, seemed to him an astounding proposition, for in plain terms it meant the origin of a new species of the lowest form of animal life—a mode of origin altogether different from anything we have been accustomed to accept. Assuming the existence of a special cancer protozoan cell, we have not yet discovered its life history outside the body. To this end numerous experiments are needed to induce the parasite to thrive under artificial conditions which would permit the study of every phase of its history. We have learned, Mr. Butlin hazarded, that it can live. To find out if it can also thrive and propagate outside the body, experiments under all sorts of conditions must be made on various animals—not only on mice.

The Imperial Research Fund, as well as the Research Laboratory in Buffalo, is occupied with the cancer problem, but as yet its labors have borne little or no fruit. We need further most careful study of cases of reputed contact cancer in the same individual, and also of alleged transmission from one person to another. In many of the latter reported cases the disease has not been the same in both persons. Not only so, it has not been even the same variety of carcinoma, for in certain cases, in one person it was sarcoma and in the other carcinoma. Of course, such instances cannot be accepted, but all reputed cases of contagion should be investigated. If this were done, Mr. Butlin said, he had a very strong impression that some, if only very few, cases would prove to be instances of real transmission of the disease. No circumstance, however small, should be disregarded in such investigations, and no obstacle is so great that it should not be boldly faced without prejudice.

THE CANTEEN BILL IN CONGRESS.

A BILL has been introduced into the Lower House of Congress, by Representative Morrell, to permit the restoration of the canteen feature in the post exchanges of the army. This bill is supported by all the true friends of the soldier in and out of the army, but Mr. Hull, Chairman of the House Committee on Military Affairs, is quoted as opposing any legislation of this nature during the present session. That is to say, if Mr. Hull has his way, the pimps, the rumsellers, the gamblers, and the prostitutes are to be given another year in which to prey upon the bodies and souls of the enlisted men, while the friends of the soldier, who, recognizing the futility of blue laws, would remove the temptation to degrading vice by giving opportunity for innocent recreation, are to be restrained by the firm hand of the law.

The reason alleged by Mr. Hull for inaction this year is the same as that expressed a year ago. He would wait, he says, until the present order of things has had a full trial! We wonder how long it will be before the divekeepers and their dupes and allies of the W. C. T. U. will admit that the present system has had a fair trial! If the roll of infraction of discipline, desertion, insanity, and death, directly traceable to the abolition of the canteen, is not sufficiently large in five years, will it be any more convincing to the illogical ladies who have so long terrorized Congress, in ten years—or fifteen?

A recent dispatch to the *New York Times* from Chicago gives some details of a grand jury investigation of saloon dives, gambling resorts, and other

disorderly places in the town of Highwood, near Fort Sheridan. The evidence introduced by Capt. M. E. Saville and other officers of the fort alleged the following state of affairs existing as a direct result of the abolition of the canteen: "Twenty-five violent deaths in eighteen months as a result of soldiers frequenting the dives. Carloads of uniforms and other equipment stolen from the fort by soldiers and sold to divekeepers for liquor. Connivance at the desertion of soldiers by divekeepers. Every saloon, with one exception, is a gambling house, and all the games are 'crooked.'" It was also alleged before the jury that certain politicians and several wealthy individuals are in a ring to prevent the Government from interfering with the "prosperity" of the village. These ringsters have also the powerful support of the Woman's Christian Temperance Union. Against this array of facts the opponents of the canteen have never, so far as we have been able to learn, offered anything tangible in proof of the alleged evils of selling beer in the post exchanges. Their arguments are based on pure assumption. It is a sin to drink beer, *ergo,* the sale of beer and light wines, even under strict limitation as to quantity, is an offense against morality. Let the men drink all the whiskey they will, while on leave, but to remove the temptation to drunkenness by sanctioning moderate indulgence on the Government reservation—never! Occasionally, it is true, a rara avis is found, even in the army, who sings a weak denial, in the face of the adverse testimony of an overwhelming majority of the officers and men, that drunkenness is any more common among the enlisted men to-day than it was in the canteen times. But such piping sounds faint through the virile roar of those who know the truth and speak it.

The real difficulty in the way of restoring the canteen at this session of Congress, according to the Washington correspondents of the *Globe* and other newspapers, is the fact that members of the House who want to succeed themselves must secure renomination and reelection within less than a year. Few of the Representatives have the courage to inject deliberately the temperance question into their campaigns. In many parts of the country a vote for the canteen by a member of the House would be the signal for a war upon him by the whiskey men and the W. C. T. U., and many a seat would be lost in consequence. Hence the reluctance shown in taking up the canteen question again.

The Association of Military Surgeons of the Unied States has memoralized Congress in favor of Mr. Morrell's bill, and the same also has the support of all the officers of the army, including the generals commanding the various departments and the chaplains, and all others, in and out of the service, who are in position to see the fearful evils entailed by the present system. The members of the House freely admit in private conversation the validity of the arguments in favor of the canteen, and we cannot but think that there will be found a sufficient number of them, guided by conscience and with the courage of their convictions, to repeal the iniquitous anti-canteen law and restore to the enlisted man the protection against vice and the miseries which indulgence in it entails, of the beneficent post exchange with the harmless canteen feature restored. Surely common sense and morality must finally prevail against blind fanaticism and the crafty play upon it of the rumsellers and divekeepers.

THE ORIGIN OF SLEEP.

That state of more or less complete physiological unconsciousness which we call sleep has formed the subject of a multitude of investigations, and numerous hypotheses have been advanced to account for the phenomenon. Among the more important theories advanced within recent years we find that in one the production of sleep is believed to depend on the accumulation of acid waste products in the blood which results in a depression of the activity of the brain cells. Another theory is based on the so-called neuron doctrine, according to which the contact between the terminal arborizations of the afferent nerve fibers and the dendrites of the cortical cells is broken by contractions of the latter, as the result of which the brain cells are cut off from external stimuli. In a third we find that sleep is attributed to a temporary anemia of the brain which depends on certain vasomotor changes, by which the greater volume of blood is shifted from this organ to the cutaneous or the visceral circulation.

The theories mentioned do not by any means include all those which have been proposed to explain the occurrence of sleep, and we may expect a number of others before the problem is solved. In a communication to the recent Italian Medical Congress, held at Genoa in October, Dr. Alberto Salmon advances the suggestion that sleep is due to the effects of an internal physiological secretion which is derived from the pituitary body. He believes that some of the hypnotic properties exerted by this structure may be due to the presence in its substance of bromine, as demonstrated by Paderi, and he considers that his hypothesis is strengthened by the fact that the administration of the glandular extract from the pituitary body is useful in insomnia. Attention is called to the fact that somnolence is associated with certain lesions of the pituitary body, among which have been noted tumors, the functional hyperactivity during the early stages of acromegaly, the hypertrophy which accompanies myxedema and sleeping sickness, and the inflammatory congestion of a slowly evolving meningoencephalitis. A similar condition of somnolence has also been noted in certain cases of acute poisoning where the secretions are all increased, as by pilocarpine, in the chronic autointoxication of hepatic or gastrointestinal origin (in which pituitary hypersecretion has been experimentally demonstrated), and in any diseased condition capable of inducing hyperemia of the pituitary body. On the other hand, according to Salmon, insomnia is met with in patients with tumors of the pituitary body which are characterized by destructive or degenerative changes, in metastatic malignant growths, in abscesses of the gland in question, in Graves's disease, in inanition or old age, in cases of poisoning marked by inhibition of the secretion, such as by atropine, etc.

Whether this small and comparatively little known structure really presides over such an important physiological function, cannot, we believe, be fully decided by the data on hand. This gland, if gland it be, probably constitutes only a link in the chain of the so-called internal secretory organs, which include among others the thyroid, parathyroids, and adrenals, and whose immediate function relates more closely to metabolic processes in the organism than to any other phenomena. If disturbances of their function

are characterized by disorders of sleep, we need not look upon the latter as anything more than a result of the abnormalities in metabolism. Then again, the writer's contention does not permit of any differentiation between states of normal and states of pathological sleep, and from our present knowledge of the subject we cannot assume that the one is merely an exaggerated or abnormal expression of the other. Those theories which ascribe the phenomenon of sleep to regular vasomotor changes seem much more reasonable in their explanation and application.

THE ETIOLOGY OF SYPHILIS.

On March 3, 1905, Schaudinn, a worker in the Imperial Institute of Hygiene at Berlin, discovered a spiral organism in the tissue-juice of a secondary papule, and gave it the name of *Spirochæta pallida.* An associate of Schaudinn's, a military surgeon named Hoffmann, had excised the papule, and the investigation of the organism was conducted jointly by Schaudinn and Hoffmann. The discovery of the spirochete came at a period when the search for the cause of syphilis had been given a new and hopeful aspect through the successful inoculation of the disease in monkeys by Roux and Metchnikoff, and since the publication in May, 1905, of the papers of Schaudinn and Hoffmann a large number of investigators have studied the new organism, so that to-day the literature on the subject is already quite extensive.

The etiology of syphilis has been a puzzle ever since the disease was known to humanity. That it is infectious was recognized early, and when the ideas of "animal contagion" began to come in vogue in the sixteenth century, syphilis was classed by some authors (Kircherius, Abercromby) among the ills of the flesh that are caused by this vague biological influence. After the discovery of "living animalcules," which are now recognized as bacteria, by Anthony van Leeuwenhoek in 1675, and after the publication of the doctrine of the pathogenic bacteria by Plenciz of Vienna, in 1762, the animalcule theory of syphilis became current. Thus the matter rested until 1881, when a special variety of cocci was discovered in syphilitic condelomas by Aufrecht. In 1885 came the announcement of Lustgarten's discovery of the bacillus of syphilis which now is generally regarded as identical with the smegma bacillus, and, therefore, of no etiological significance in the causation of venereal diseases. Since Lustgarten's announcement, a great number of germs and other microorganisms have been described as occurring in syphilitic lesions, and as more or less connected with the cause of the disease.

Among the organisms described spirochætæ were mentioned as early as 1857 by Donne, while Bordet and Gengow state that they had seen the spirochete three years before Schaudinn's paper appeared, but as the organism was not present in all cases, no further study was made at the time. A Russian observer, Omeltchenko, also claims to have seen the spirochetes twelve years ago in numerous specimens from syphilitic lesions, but mistook them for minute fibrils of fibroelastic tissue.

Schaudinn and Hoffmann found two varieties of spiral organism, the first of which, *Spirochæta pallida,* occurs only in syphilitic lesions and is a delicate, long, thin spiral, pointed at both ends, and markedly motile. It has numerous and regular spiral turns, and stains very faintly. The second variety, *Spirochæta refringens,* is found in decomposing secretions about the genitals, and also occurs along with the other in syphilitic lesions. It is probably saprophytic, like the smegma bacillus, and is a larger spiral with fewer turns, rather more wavy than corkscrew shape, and stains more deeply. The pallida was found in chancres, in condylomata, in inguinal glands, and in the blood from the spleen. It was absent in non-syphilitic control-material.

Since the publication of the researches of Schaudinn and Hoffmann, a number of observers have offered confirmatory evidence. Metchnikoff and Roux found the spirochete in a chancre in a monkey inoculated with syphilis. The organism has been found in congenital syphilis, and in the blood of secondary syphilis. It seems to be constantly present in primary and secondary lesions, although sometimes in such small numbers as to evade any but the most careful search. It seems, however, to be absent in tertiary lesions.

In this country, the first investigation published on this subject was, we believe, that of Dr. Fanoni. This author confirmed the results of Schaudinn and Hoffmann, and published a study of fifteen cases of syphilis. In two of these he failed to find the spirochete, but both had been under treatment for some time. In two control cases, non-syphilitic in character, this organism was absent. It was present, however, in all the primary lesions examined, and also was found in the inguinal glands, in condylomata, in mucous patches, and in the tonsils. The finding of the organism in the tonsils was especially interesting, as it was the first attempt to demonstrate the new organism in tonsillar tissue. Preliminary reports on the same subject have appeared within the past few weeks in various American medical journals, indicating that a number of other observers are now working in the same direction. In the Wesley M. Carpenter lecture recently delivered at the Academy of Medicine (Medical Record, November 11, 1905), in which a résumé of the entire subject was given, Dr. Simon Flexner stated that the Rockefeller Institute is now conducting an extensive investigation on the same theme. Dr. Flexner concludes, from a study of a number of cases in which the spirochete was found, that while we are as yet not justified in declaring that the organism is pathogenic for syphilis, the investigations thus far published certainly encourage the hope that we are at last upon the right track. However, so many other organisms have been described as causes for syphilis in the past that it behooves us to be conservative. The medical world will watch with interest the investigations now in progress, but for the present the verdict cannot be rendered.

Fighting the Noise Evil.

Urban life has its discomforts as well as its pleasures, and those who would have the latter must put up, as patiently as may be, with such of the former as are unavoidable. But this does not mean that what can be cured must be endured—quite the contrary, for the nuisance makers are so callous to the misery they cause that unceasing vigilance is needed to curb their persistence. Among the greatest of the inflictions of city life are the noises, some of

which are unavoidable; many, however, can be reduced or silenced altogether. The reason why they are allowed to continue is that the maker of illegal noises never voluntarily abates his own nuisance and yields only to compulsion of the most emphatic sort. This compulsion comes as a rule only when the public conscience is aroused. But the awakening of the public conscience is no easy matter, and one who would attempt it must be endowed with energy and perseverance of no mean order. The truth of this is shown in the crusade, initiated by Mrs. Isaac L. Rice, against the unnecessary whistling of tugboats navigating the rivers which encircle Manhattan Island. For years this whistling has been kept up with supreme disregard of the rights of citizens, and until this lady took the matter up and organized a public protest against the practice there seemed to be no possible chance for relief. The nuisance has not been stopped and we are not sure that it ever will be, but if untiring energy can win a battle this one will some day be won. Mrs. Rice has collected a mass of most convincing evidence regarding the needlessness of much of this noise, the extent of the evil, and the injury which it works to the health and comfort of a large number of our citizens who live along the water front. Some of the greatest sufferers are the inmates of the public hospitals and other city institutions located near one or the other river or on the islands. The superintendents and other officials of hospitals and asylums, having an aggregate of about 12,500 inmates, have certified to the fact of this nuisance and the injurious effect of the noise upon the health of the patients. The magnitude of the evil is shown by a count which was made during the night of December 22-23. On that night, with perfectly clear sky, a watcher, stationed near 89th street on the Riverside Drive, counted 3,119 blasts by tugboats and other steamers between the hours of 10 P.M. and 7 A.M. The unnecessary nature of the nuisance is shown by statements of scow captains, dock watchmen, and others who testify that the whistles are not blown for the most part as signals to passing steamers for right of way, but to wake up watchmen on the piers, to signal to scow captains in the tow, to call deckhands from saloons in the neighborhood, and so on. One great obstacle in the way of the suppression of this evil is that the municipal authorities have no jurisdiction over the tug captains, the navigable waters encircling the city being under the control of the Federal Government. Washington is out of earshot of the whistles, the Health Commissioner of New York is without authority to cause the arrest of the culprits, and consequently the tugboat captains are indifferent to the complaints of the sufferers from their insolent noises. No argument is needed to prove that sleep-disturbing noises are prejudicial to the health of the well and productive of serious injury to the weakened nervous constitution of the sick and convalescent. Mrs. Rice is doing a good work, and if she meets with the success which her public-spirited crusades deserves, she will receive the thanks not only of those whose slumbers are disturbed by the screeches of the steam whistles, but also of the twelve thousand sick in the public institutions whose restoration to health is imperiled by these unnecessary noises. It is possible also that the efforts of this energetic lady may have even more far-reaching and beneficent consequences. If the tooting tugboat captains are compelled to moderation, sufferers from other city noises may be encouraged to protest and to act, and perhaps some day even the "flat" wheels of the trolley-cars may cease to pound.

The Evil Eye.

Crimes committed by the Italians in our country are often so cruel in the manner of their commission and so unaccountable in purpose that many people have assumed that there lurks in the Italian breast a thirst for blood and a mania for the taking of life. On the contrary, the Italians, as a race, are happy, kind-hearted, and intensely religious, although they do not hold life as sacred as do other nationalities. In some instances the taking of a life is regarded by the superstitious among the lower classes as a philanthropic duty. This fact was elicited recently in the investigation of a murder by the coroner of San Francisco, more especially from the testimony of an Italian physician of prominence in the city. A man was suspected of having taken the life of his sister-in-law, but apparently there had been no motive for the crime. The physician explained, however, that there is, among the poorer class of his people, almost universally a superstition known as the evil eye. The possessor of this peculiar organ is believed to have the power to inflict an endless succession of misfortunes upon his associates in a manner far more subtle than can be attributed to mere hypnotism. Hence, when misfortunes begin their multiple march through the Italian household, each recurrence becomes an added evidence of the ocular witchcraft. Resort is had to penance and prayer, and the testimony in the present case showed that hundreds pray daily in the churches of the Italian quarter of San Francisco for deliverance from the evil eye. The murderer had become practically a religious monomaniac, and after three years of devout and persistent, but unanswered prayer, he had finally decided, as a matter of duty, to put an end to the misfortunes of his family by murdering the possessor of the malicious eye; for it had been decided long before by himself and his wife that the source of their distress rested in the orbit of the sister-in-law. The plea of insanity will, no doubt, be entered for the accused, but more important than the decision of this case will be the effect of the revelation upon those who have long been in a position to enlighten the minds of these simple people but have neglected to do so.

News of the Week.

Popular Lecture at the Academy of Medicine.—Health Commissioner Darlington's popular lecture on cerebrospinal meningitis and pneumonia, delivered at the Academy of Medicine on December 29, was well attended. In speaking of the former disease he stated that the mortality in the epidemic of last winter was 91 per cent., and there were 344 deaths out of the 365 cases reported. He said that a fair conclusion was that the recent apparent increase of pneumonia had been mainly due to the transfer of part of the bronchitis mortality record to the pneumonia record, either as a matter of classification by registrars or of diagnosis by physicians, or both. While the figures did not bear out the belief that pneumonia was on the increase—showing, in fact, just the contrary to be true—it was important to remember that the general death rate for all diseases had decreased by about one-fourth. The decrease, therefore, in pneumonia had not kept pace with the general improvement in the health of the inhabitants of the countries and cities for which the inspector had given figures. He rehearsed the conclusions reached by the meningitis commission and expressed an optimistic opinion regarding the prophylaxis

of the disease. Subjects proposed for other popular lectures at the Academy of Medicine are patent medicines and the New York city water supply.

Philadelphia's Paupers.—Much unfavorable newspaper comment has lately been circulated concerning the manner in which the paupers are cared for at the Philadelphia Almshouse and Insane Pavillion, known locally as Blockley. The sanitary conditions throughout the buildings are said to be bad, and there is apparently great inadequacy of supplies in all departments. For example it is alleged that there are but 300 pairs of stockings for 302 women patients, and only 269 pairs of shoes for 919 inmates who are able to go about. Other articles of apparel are provided on the same scale, so that when washing day arrives, according to the accounts in the newspapers, some of the patients have to stay in bed until their garments have been returned to them. Conditions are stated to be especially bad in the consumptive wards where the measures usually considered essential in the care of tuberculous patients cannot be carried out.

Campaign for Pure Milk.—The Chicago Woman's Club has taken the initiative in a campaign for pure milk. It is contended that the milk is not pure when it leaves the farms, owing to the unsanitary conditions of many of the country dairies. The women's clubs of Cook County have been called upon to subscribe $1500 annually to pay the salary of a competent inspector of milk.

Pennsylvania State Medical Examinations.—According to the report of the Pennsylvania State Board of Medical Examiners there were 56 failures among 460 candidates for the license to practise within the State. The candidates represented 38 colleges, including the Universities of Naples, Florence, and Turin, and the Western University of London, Ont. Four candidates were expelled for cheating.

Vermont Tuberculosis Sanatorium.—A site has been selected for the sanatorium for incipient tuberculosis to be presented to the State of Vermont by Senator Redfield Proctor. The location chosen is in the town of Pittsford about a mile and a half from the Rutland railway station. The building will be started in the spring and it is expected that it will be ready for occupancy next winter.

Boston Medical Library.—At the annual meeting of the Boston Medical Library, held on November 14, Dr. John W. Farlow was elected Librarian, to succeed the late Dr. James R. Chadwick.

Mayor McClellan's Appointments.—The following appointments, of special interest to physicians, have been made by the Mayor upon entering on his second term of office: Commissioner of Health, Dr. Thomas Darlington; Street Cleaning, Dr. John McG. Woodbury; Tenement House, Edward J. Butler; Charities, Robert W. Hebberd. Of these, all but the last are reappointments.

American Dermatological Association.—At the twenty-ninth annual meeting of this association, held in New York City, December 28, 29, and 30, 1905, the following officers were elected for the ensuing year: *President*, Dr. M. B. Hartzell of Philadelphia, Pa.; *Vice-President*, Dr. Thomas C. Gilcrist of Baltimore, Md.; *Secretary and Treasurer*, Dr. Grover W. Wende of Buffalo, N. Y. The next meeting of the association will be held in Cleveland, Ohio, in May, 1906.

A Medical Peace Society.—Under the title of the "International Medical Association to Contribute to the Suppression of War" an international congress of medical men is being organized in Paris. It is the object of the society to protest against armed conflicts, and to assist the work of settling international disputes by arbitration. It is proposed to have the date of the congress coincide with that of the Sports Exhibition to be held in Paris in 1907. The president of the association is Dr. J. Riviere, 25 Rue des Mathurins, Paris, to whom applications for membership should be sent.

Death Rate for 1905.—The New York City death rate for 1905 is next to the lowest on record, and the number of deaths from contagious diseases is the lowest yet recorded. In 1905 there were 103,852 births, against 99,555 in 1904, an increase of 4,297. There were 42,667 marriages, against 39,436 in 1904, an increase of 3,231. The deaths in 1905 were 73,450, against 78,060 in 1904, a decrease of 4,610. The death rate per 1,000 of population in 1904 was 20.01, but this year it was reduced to 18.25. The real saving of life, considering births and deaths, was 7,042.

Hospital Fires.—A fire which did $500 worth of damage recently started in the engine room of the Cumberland Street Hospital, Brooklyn, but was extinguished without alarming the patients. A more serious conflagration in a building across the street from Bellevue Hospital caused some alarm among the patients in that institution on December 29.

Post-Graduate Hospital Report.—The annual report of the New York Post-Graduate Hospital shows a deficit of $21,678.82 for last year. The hospital proper in 1905 treated 3,579 patients, of whom at least 70 per cent. were absolutely free patients. Of the others the majority contributed $10 a week for their support and treatment, which is about $8 a week less than the cost. There were 95,142 free visits by patients to the dispensary, and 21,519 patients were treated free in that place. The total number of free days of hospital care for all patients was 43,276. The hospital hopes soon to be able to cancel its entire debt.

A Case of Alleged Superfetation.—A remarkable story comes from Albany to the effect that a woman of twenty years has recently given birth to a child 116 days after having been delivered of another infant. Both children are said to be normal by the physician who conducted the second labor. The first was attended only by a midwife

Nasal Intoxication.—According to the Norwegian papers an economical method of producing alcoholic intoxication is being practised by the lowest classes of Christiania. The toper fills the palm of his hand with a very strong form of corn brandy and snuffs it up into the nose. This is repeated several times, though once is sufficient to produce complete intoxication.

Legacy to Harvard Medical School.—Harvard University will benefit to the extent of $50,000, to be applied to the needs of the Medical School, by the will of Dr. George S. Hyde. The legacy will be turned over to the college on the death of Elkin P. Hyde and Mrs. Annie M. Sargent, brother and sister, respectively.

Eastern Medical Society.—At the last regular meeting of the Eastern Medical Society, held on December 8, 1905, at the Society's rooms, Clinton Hall, 151–153 Clinton street, the following officers were elected for the year 1906: *President*, Dr. Charles Goodman; *First Vice-President*, Dr. N. M. Mandl; *Second Vice-President*, Dr. A. J. Ron-

ginsky; *Recording Secretary*, Dr. Martin Cohen; *Corresponding Secretary*, Dr. I. S. Tunick; *Treasurer*, Dr. W. M. Stark. The next regular meeting will be held on January 12, 1906.

A New Hospital in The Bronx.—The will of the late Charles T. Yerkes gives a sum, not to exceed $800,000, for the purchase of ground and the erection thereon of a hospital in the Borough of The Bronx. The will also provides for an endowment fund of about five million dollars, the income arising from which is to be used for the support and maintenance of the hospital. It is stipulated that the institution shall "be open to the public without regard to creed, race, or color, and under such directions as the Trustees or Directors of said hospital may prescribe by rules; and any patient received or admitted to said hospital whose financial means at command are not such as to enable said patient to pay for the necessary treatment and care shall be treated and cared for therein without any expense or charge whatsoever."

Blue Earth County (Minn.) Medical Society.—The annual meeting of this society was held at Mankato on December 19, and the following officers were elected: *President*, Dr. J. S. Holbrook, Mankato; *Vice-President*, Dr. John Williams, Lake Crystal; *Secretary*, Dr. A. G. Liedloff, Mankato; *Treasurer*, Dr. Lida Osborn, Mankato.

Sonoma County (Cal.) Medical Society.—At the recent meeting of this society, held in Santa Rosa, the election of officers resulted as follows: *President*, Dr. A. McG. Stuart; *Vice-President*, Dr. J. H. McLeod; *Secretary*, Dr. Elizabeth M. Yates; *Treasurer*, Dr. Lizzie Lain.

Grafton County (N. H.) Medical Society.—At the annual meeting of this society held at Woodsville, December 12, the officers elected for the coming year were: *President*, Dr. W. J. Beattie of Littleton; *Vice-President*, Dr. F. von Tobel of Lebanon; *Secretary and Treasurer*, Dr. George A. Weaver of Warren.

Maine Academy of Medicine.—The following officers were elected at the annual meeting of the Maine Academy of Medicine and Science, held in Portland on December 13: *President*, Dr. C. A. Peaslee, Bath; *Corresponding Secretary*, Dr. A. H. Little; *Statistical Secretary*, F. Y. Gilbert; *Assistant Secretary*, Dr. Gilman Davis; *Treasurer*, Dr. Bertrand G. March.

Southern California Medical Society.—At the semi-annual session of this society, held in Los Angeles on December 7, the following were elected as officers: *President*, Dr. Howell Tyler of Redlands; *Vice-Presidents*, Dr. Frank Garcelon and Dr. Roberts of Pasadena; *Secretary*, Dr. Key of Los Angeles.

Jefferson County (Ky.) Medical Society.—The following officers were elected at the recent meeting of this society in Louisville: *President*, Dr. J. J. Moren; *Vice-President*, Dr. S. J. Myers; *Treasurer*, Dr. Edward Speidel; *Secretary*, Dr. J. Hunter Peak.

Jackson County (Mich.) Medical Society.—These officers were elected at the meeting of this society, held in Jackson on December 7: *President*, Dr. A. J. Roberts; *Vice-President*, Dr. J. C. Kugler; *Treasurer* Dr. F. W. Rogers; *Secretary*, Dr. R. G. Hendrick.

Hancock County (Ohio) Medical Association.—At the meeting of this society, held in Findlay, on December 14, the following officers were elected for the ensuing year: *President*, Dr. E. G. Hersh of McComb; *Vice-President*, Dr. Treece; *Secretary*, Dr. Nelia B. Kennedy; *Treasurer*, Dr. J. P. Baker.

Huntington County (Ind.) Medical Society.—These officers were elected for the ensuing year by the society at its recent meeting in Huntington: *President*, Dr. S. V. Wilking of Roanoke; *Vice-President*, Dr. W. C. Chafee of Huntington; *Secretary* and *Treasurer*, Dr. Ervin Wright of Huntington.

Obituary Notes.—Dr. A. C. Hardin of Elkton, Ky., died on December 20 from the infirmities of old age. He was aged seventy-five years. He moved to Elkton in 1873 and practised until about fifteen years ago, when his eyesight became affected.

Dr. R. H. Tullis of Lawton, Oklahoma, died on December 14 of typhoid fever at the age of forty years. He was, at the time of his death, president of the State Medical Association of Oklahoma, vice-president of the Central Medical Association, vice-president of the Comanche County Medical Association, and a member of the City Hospital Association.

Dr. John R. Crapo of Terre Haute, Ind., died on December 18 of diabetes. Dr. Crapo had practised medicine in Terre Haute for thirty-eight years. He was born near Sullivan, October 3, 1850.

Dr. J. M. Waddick, one of the oldest citizens of Toledo, Ohio, died of heart disease on December 12. Dr. Waddick was sixty-eight years old and had spent many years in the city of Toledo, where he had held many positions of trust.

Dr. John H. Sanborn of Franklin Falls, N. H., died on December 19 in consequence of a paralytic stroke. Dr. Sanborn was born in Meredith, in 1830, the son of Dr. John Sanborn. He began the study of medicine with his father in Meredith and studied also with his brother, Dr. J. A. Sanborn of Plymouth, and with Prof. B. R. Palmer of Vermont Medical College of Woodstock, Vt. He was graduated from the Berkshire Medical Institute at Pittsfield, Mass., in 1852. He practised his profession in Alstead until December, 1855, and in Meredith until he enlisted as surgeon in the Twelfth New Hampshire Volunteers. After the war he resumed his practice in his native town for several years and then removed to Franklin, where he soon established an enviable reputation and became well known as one of the best read physicians of the old school and a prominent citizen.

Dr. Charles A. Williams, a pioneer physician of Chicago, died on December 18 at the age of sixty-six years. He was born in Caledonia, N. Y., in 1840, and came to Chicago fifteen years later and graduated from Hahnemann Medical College in 1861.

Dr. William Maxwell White of Amsterdam, N. Y., died December 29, of pneumonia. He was forty years old. He was a graduate of Union College, 1881, and the Albany Medical College, 1885. He was a son of the late Dr. Joseph M. White.

Dr. B. W. Taylor of Columbia, S. C., died on December 27, of pneumonia at the age of seventy-two years. His grandfather was a Colonel in the Revolution. Dr. Taylor was a Colonel in the Confederate Army on General Hampton's staff, and was the chief surgeon in Charleston Harbor at the fall of Fort Sumpter. At the close of the war he was Surgeon-General of Cavalry of the Army of Northern Virginia.

Dr. J. Hodges Drake of Asheville, N. C., died on December 15 at the age of thirty-six years. Dr. Drake went to Asheville from Opelika, Ala., five years ago.

Dr. Thomas Gibson of Twiggs County, Ga., died on December 11. He was born in 1819 and had been in practice since 1838, continuing in active work until the onset of his last illness. Dr. O. C. Gibson of Macon, Ga., is his son.

Dr. Benjamin Blockford, for fourteen years superintendent of the Western State Hospital at Taunton, Va., died on December 13, at the age of seventy-one years. He was a native of Lynchburg, Va.

Dr. C. C. Clements of Springfield, Mo., died on December 20, after an illness of two weeks. Dr. Clements was born April 4, 1838, at Clementsville, Tenn., and before the war attended Louisville, Ky., Medical College. Afterwards he also attended Jefferson Medical College at Philadelphia, Pa. During the war, from 1861 to 1865, he served in the Union Army, first as captain of a cavalry company, then as brigade surgeon with the rank of major. At the close of the war he resided for two years at Paris and Sherman, Texas, whence he came to Springfield in 1868, from which time he successfully practised up to his last illness.

Dr. William W. Gardner of Springfield, Mass., died on December 11, at the age of seventy-nine years. After serving in the Mexican war he received his medical degree from the Worcester Medical College in 1849, and settled in Pittsfield. He went to Springfield in 1860 and after some time spent in further study in New York, he made a specialty of ophthalmology, which he practised exclusively after 1875.

Dr. John Campbell, Brigadier-General and Surgeon U. S. Army, retired, died at his home at Cold Spring, N. Y., on December 25, 1905. He was born in Albany, N. Y., on September 16, 1821. He was graduated from the Albany Medical College and in 1847 he entered the U. S. Army as Assistant Surgeon. He served through the Mexican War on General Scott's staff, participated in Indian campaigns, and served through the Civil War, during which he was twice brevetted for faithful and meritorious services. In 1885 he was retired for age, with the rank of Colonel and Surgeon. Last year his rank was raised to Brigadier-General. He is survived by a wife, six sons, and two daughters.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL FUNDS AND MANAGEMENT—A DANGER OF SOFT WATER—FOG AND SMOKE.

London, Dec. 15, 1905.

At a meeting of the General Council of King Edward's Hospital Fund the reports of the executive and distributor's committees were adopted and cheques for the grants awarded were posted last evening. The total amount this year is £100,000, as against £79,000 in 1904. A strong conviction is expressed of the undesirability of new hospitals being opened without the fullest consideration of their necessity and the means of maintaining them. This expression will, perhaps, operate as a warning to those who propose such action, that they will not be assisted by this fund.

Following the example of the Sunday fund the committee will in all such cases require the institution to have been maintained for three complete years before any application can be entertained. This determination will commend itself to the profession, for no well-informed person can doubt that we have far too many small hospitals and dispensaries. Some have done long and good service, but the value of others is nil. Of the latter some have grants, so that the list might very well be revised; but of course it is no easy task to estimate the relative importance of 106 institutions, and though some persons are dissatisfied, the difficulties of the committee should be fairly considered.

The propriety of amalgamation is again urged in the report, and the committee evidently intends to use further pressure in this direction. It may, however, seem to many unjustifiable to devote money subscribed for hospital maintenance to promote this union or to give sums towards buildings or the extinction of debts. The policy of the Council is, however, to exercise control over managers in all directions that tend towards efficiency, and the committee expresses its views on a variety of points. Thus the transfer of teaching preliminary and intermediate subjects is applauded and the cost of removing King's College Hospital to South London is aided to the extent of £11,000. A special grant is voted to the Great Northern Central to purchase freehold ground adjoining. West Ham Hospital has lately acquired an adjoining building and £2,500 is voted for furnishing it—a sum which certainly seems, at first sight, excessive and which illustrates the extravagant ideas of hospital managers as to the requirements of patients in the way of costly equipments. The fact is mentioned that in some cases grants have been made towards building schemes which have not been carried out. This looks like clear proof that such extensions were not really required. An equally significant fact is that in some cases grants allocated to the reopening of beds have not added to the permanent accommodation, inasmuch as other wards have been subsequently closed. Could anything so reprehensible have been anticipated from hospital managers? In other cases the hospitals to which grants for reopening have been made no longer need help in this way. The committee think it therefore time for making a change and no longer dividing grants into subscriptions and donations. The fund has now attained a permanent income of £50,000 a year, and therefore can meet all its engagements for annual amounts. An interesting letter was read by the Duke of Fife from the Prince of Wales, who for the first time had (in consequence of his absence in India) been unable to preside at the meeting.

It is not often that complaint is made of water being too pure. From Birmingham, however, I hear that the water brought at vast expense from the Welsh hills is so soft that it has a serious effect on galvanized cooking vessels, in consequence of which the health committee has decided to ask manufacturers to recall any such utensils which they have sent out for sale in the city. The solvent effect of soft water has long been recognized, but it was not expected that the Birmingham supply would prove so active.

In London some genuine old-fashioned fogs have interfered with business and pleasure and set people talking again about smoke prevention. Everyone is for prevention just now, but I suppose the excitement will give way once more to other topics.

OUR BERLIN LETTER.

(From our Special Correspondent.)

HONOR TO KOCH—BERLIN HOSPITALS OPENED FOR MEDICAL STUDY—DIAGNOSTIC VALUE OF THE ROENTGEN RAYS—RELATION OF PANCREATIC DISEASE TO DIABETES—EXPERIENCES OF GERMAN SURGEONS IN THE RUSSO-JAPANESE WAR—THE BLOOD IN LEAD POISONING.

Berlin November 25, 1905.

The Medical Society opened its session this winter without a vice-president, for Wiesenthal the old, well-known physician died during vacation. At about the same time Koch returned from his successful trip to Africa, and there was a general desire to honor him by electing him to this office. It has been the custom to appoint a general practitioner to this position, and many did not like any innovation. However, since Koch was a general practitioner before he began his bacteriological studies, and since his life has been a generally useful one, he was nominated on October 22, and accepted a few days later.

Berlin has opened her hospitals for medical instruction, and the courses of study in her institutions are much improved. In the future the hospitals are to be opened for lectures and courses which will be given by the physicians connected with them. Up to the present time there were certain courses for Berlin physicians but only a few for students. This régime is very valuable for those hospital physicians who are also professors in the University, as well as for the medical world in general.

A further advance in medical affairs arranged by local authorities is the opening of a central bureau in the City Hall which gives information to all desiring to know about vacancies for patients in the hospitals. Special telephones will connect the bureau with the hospitals. This bureau will also control the transportation of patients.

Apropos of the value of the Roentgen rays in diagnosis, there were presented very interesting results of investigations by this method at the meeting of the "Vereinigung der Charité Aerzte" on November 15. De la Kamp spoke on tuberculosis of the mediastinal and bronchial glands. Twelve hundred children were examined by the Roentgen rays. In these cases the discovery of tuberculous glands by the ordinary methods of physical investigation was very rare. The results of the examinations by the Roentgen rays are not always absolutely certain, but the Roentgenograms are a great improvement on the old methods. Various difficulties may be avoided with practice, one of which is the confusion of the alterations in bones and carti-

lages due to rachitis with diseased glands which they resemble. The writer declares that the tuberculous glands of the bronchial system and of the mediastinum which are made visible by the Roentgen rays do not correspond with the palpable glands of the neck.

Steyer spoke at the same meeting concerning the position and the shape of the stomach. By using bismuth he has studied the position and the form of the stomach by means of the Roentgen rays after stopping peristaltic movements by the use of opium. He agrees with Doyen that the stomach may be generally considered as assuming a vertical position and that its shape often resembles that of an hour-glass. This theory will not support the former idea of the existence of an enteroptosis when the stomach reaches to the navel since the normal stomach often falls below this landmark.

Great interest attaches to Hirschfeld's paper on the diseases of the pancreas in diabetes which was read November 8, before the "Medicinische Gesellschaft." The diagnosis of pancreatic disease during the course of diabetes has always been considered very difficult. Indeed, this affection was formerly diagnosed in those cases of diabetes only, which were in the last stages. Now the effort is made to diagnose this complication in cases which are not severe. The speaker presented the following points which he thought valuable in clearing up the diagnosis: The disturbance in the albumin and fat; the pain which resembles that in the crisis of gallstones or angina pectoris; the question of the presence of gallstones need not be considered if the liver is not painful, if the pain is more confined to the left side of the body, and if jaundice is absent the function of the circulatory organs is disturbed, for even if the patients drink generously, the amount of urine is not increased, neither is there any alteration in the function of the stomach, the heart, or the kidneys. There is often present persistent edema and the patients experience great discomfort after drinking much liquid. The secretion of saccharum and acetone is often increased. The prognosis of such cases is grave on account of the frequent attacks of pain which are followed by an increase in the secretion of saccharum for the danger of coma in this condition must be considered.

The German physicians who were sent out to the front in Eastern Asia have nearly all returned. Brentano the chief of the German Red Cross Hospitals on the Russian side spoke concerning joint injuries at the "Vereinigung des Chirurgens Berlins," on November 11. The soldiers who were wounded in the battle of Mukden in general were not in good condition because they were brought in as a rule after six days of difficult marching, the transportation being very bad. They were partly or not at all bandaged. However, with all of these drawbacks, out of twenty-eight injured joints sixteen were not infected, only twelve patients showing an increased temperature. The wounded soldiers could give no information as to the direction or the distance from which the shot came. The sixteen cases which were not infected presented a smooth round wound as if the shot had come from a distance. Diagnosis was made on account of the pain in the joints, exudation, the discharge of synovial fluid from the wound and by its direction. In cases in which the ball was fixed in the joint it was always extracted, and although it was surrounded by a dark serous exudation the wound healed by first intention. All other cases without complications were treated by fixation bandages and afterwards by massage and gymnastic exercises. None of these soldiers, however, could return to the front because of the persistent disturbance of the joint's activity. The twelve infected cases had been, as a rule, wounded by shots from the artillery and infantry at a short distance. Long incisions in the capsule, and as rare disturbance of the bandages as possible, met with the best results. The fenestrated plaster-of-Paris bandage with iron bridle, or palm leaves softened in hot water, interposed, were found to be the best. Four cases out of five infected with tetanus died.

The well-known blood investigations of Grawitz seem to be yielding practical results. This opinion is strengthened by his paper concerning personal prophylaxis in relation to lead poisoning which was read on October 25, before the "Medicinische Gesellschaft." Lead poisoning induced by the inhalation of lead (powder or fumes) or by the introduction of lead particles into the stomach can be absolutely avoided by hygienic means, according to the writer. This intoxication is very grave for two reasons: The lead worker does not become accustomed to this poison slowly, and lead poisoning does not confer immunity but even predisposes the patient to severer attacks. A sure sign of lead poisoning is the granular degeneration of the red blood cells. This sign differentiates an attack of lead colic from other affections. Seventy lead workers who had been poisoned by lead have been examined, and in most cases this symptom has been found. Consequently the speaker proposed to practise prophylaxis in this affection as is done in malaria. That is, he believes that regular blood examinations ought to be made and those patients who show such degeneration of the blood cells should be removed from their work and be treated with purgatives and baths.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

PERFORATION IN TYPHOID FEVER—PATHOLOGY OF PLAGUE—VACCINATION AGAINST PLAGUE—REORGANIZATION OF THE HEALTH DEPARTMENT OF THE ISLANDS—PERSONAL.

MANILA, P. I., November 22, 1905.

THE November meeting of the Manila Medical Society was held at St. Paul's Hospital at 8:30 P. M., the sixth instant.

A paper entitled "A Report of Two Cases of Typhoid Fever, with Perforation and Operation" by Dr. J. B. Thomas, formerly Attending Physician and Surgeon of theBaguio Sanatorium, was read by the Secretary. He reported that the operations had been done under most unfavorable circumstances, and considering the conditions by which he was surrounded, he believed that a mortality of fifty per cent. was rather favorable. Both of the cases occurred in Japanese laborers who worked in the vicinity of the sanatorium.

Dr. Maxmilian Herzog sketched, in a short talk, the pathology of plague, as he had found it at the Government morgue, where he had been holding autopsies during the past two years. In general, his description corresponded closely with that found in the standard text books. A point to which he invites attention, so far as the pathology of plague is concerned, was the finding of hyaline fibrin thrombosis of the glomeruli of the kidneys. He found this condition in seven out of twenty cases which he studied microscopically. He also believes that bubonic plague is, as a rule, not a true septicemia, but a local lymphatic infection, and that the universal dissemination of the infecting bacilli through the blood current generally only occurs during the agonal stage.

A paper entitled "Human Vaccination Against Plague" was read by Dr. Richard P. Strong of the Bureau of Government Laboratories (now known as the Bureau of Science). He stated that his paper should only be considered as a preliminary report, and that when his research was entirely completed, he would prepare a more detailed paper. He has been working with plague bacilli for the past two years, with the view of attenuating them, so that they could be injected into human beings with safety, and now feels that he has entirely succeeded. He stated that he had a true vaccine, in that he uses the living plague organisms in his protective inoculations. His experimental work has been conducted almost entirely upon rats, and he has been so successful in protecting them against plague by vaccinating with the living attenuated plague organism, that when the rats are inoculated later with a dose of plague culture that would be absolutely fatal to an unvaccinated rat, it apparently has no effect upon a protected animal. He conducted some experiments upon a gorrilla, but reported that he was unfortunate in injecting too large a dose of plague, with the result that the animal died. An interesting point observed at the autopsy, however, was that the spleen showed only a few scattered organisms in each microscopic field, while the spleen usually contains enormous numbers of bacilli in unvaccinated plague cases.

With a view to conducting the Government more economically, the Governor-General, about six months ago, appointed an organization committee which was to make a thorough examination of the workings of each Bureau and recommend a plan that had for its object the lessening of the running expenses without decreasing the efficiency of the work carried on. The committee made its report some months ago and the Commission has taken action upon the same. The majority of the recommendations which were adopted became effective November 1, 1905. Some of the new legislation which is of interest to the medical profession is the change made in the medical departments of the Government. The Board of Health, as a board, was abolished, and there was substituted instead, a Director of Health, who has all the duties and powers heretofore conferred upon the Board of Health for the Philippine Islands. It is thought that by consolidating the authority all under one head, and holding that official strictly responsible, for everything that occurs, the shifting of responsibility which necessarily takes place in board administration can be avoided; furthermore, action by a board is necessarily slow, whereas, the very nature of the conditions in the Philippine Islands requires prompt action. The management of the infectious and contagious diseases being cited as an example where quick work may result in avoiding an epidemic. So far as known, this plan of health organization has not been attempted often in the United

States, the State of Pennsylvania being probably the only exception, and there the bill putting the plan into effect was only passed by the last legislature. The experiment here will be watched with considerable interest.

In addition to the duties heretofore performed by the Board of Health, there is now concentrated under the Director of Health the sanitation of the insular and provincial prisons, the Civil Hospital, as well as the Baguio Sanatorium of Benguet. It will therefore be seen from the foregoing, that with the exception of a few minor medical matters, the entire medical work in which the Government is interested is now vested under one head. This change is a distinct advance, for the reason that it places a professional head in charge of medical matters that have heretofore been controlled by laymen.

Dr. Maxmilian Herzog has returned from his trip to Japan, where he had gone about two months ago, for the purpose of making a special study of beriberi.

THE FEE QUESTION.

To the Editor of the Medical Record:

Sir:—It seems to me that the correspondence here presented is worthy of publication, as representing rather typical attitudes on two sides of a common question. The recipient of the bill was surprised at the amount charged, and I was surprised at the points of view taken in the case by an educated woman of generous and kindly nature. As a matter of curiosity the letters were referred to three representative surgeons in three cities at a distance from New York, in order to determine their feeling in the matter.

There is a certain degree of demoralizing influence upon the family physician when he fears to call in consultation the men whom he would choose, on the ground—and a well taken one—that he is likely to be held to account for the layman's views about the charges. Several physicians who send me their poor patients say that they do not dare to send others, because appropriate charges are too apt to be misunderstood, and they ask me to make maximum bills smaller. I would like very much to please these physicians, but the weakness and the strength of our profession lies in our desire to please, and one must be careful not to jeopardize the best interests of his colleagues. It would increase my income by many thousands of dollars annually to accede to the request, but there is a matter of principle involved. When dignified fees are charged and the reasons for them appreciated, we shall have more endowments for our medical educational institutions, and more public spirit directed toward our profession. The man who believes that he is the subject of an overcharge simply "because he had the money" is not a fit subject for approach on the matter of endowments; while the same man properly informed might be our best ally.

There is no doubt that people in comfortable circumstances are daily targets for overcharge of many kinds, and no one knows this better than the doctor who has himself acquired a competence, and who is generally considered to be an "easy mark." Well-to-do members of society must constantly stand on the defensive for self-protection. It is the fault of the medical profession if we allow colleagues really to make overcharges, or, on the other hand, to allow laymen to believe that fair charges ever belong to that category. In an ordinary case of dyspepsia it sometimes costs more than one hundred dollars just to get a diagnosis of the reasons for the symptom; but the layman is apt to think that a dollar a bottle for something advertised in the daily press is about the right figure, and most dyspeptics will suffer for a lifetime, or even commit suicide, rather than undergo the expense of accurate methods for getting relief. The family physician who tries to direct them aright may soon find himself out of practice and his patients at the drug store.

What is an overcharge? Take this case of appendicitis in question for example. Fifteen years ago I would have made a long incision, flushing out the peritoneal cavity, and employing iodoform gauze packing. The work would have required half an hour of time at least. The patient would probably have had a ventral hernia at the site of the long scar, if he did not die from insidious iodoform poisoning mistaken for septicemia, or from ileus caused by the presence of the gauze, or from sepsis allowed by the lessened natural resistance due to such treatment. It is a very easy matter for the surgeon to produce death, in a case of gangrenous appendicitis. Five hundred dollars would have been an overcharge for that sort of treatment. As it was, the operation was done in a few minutes, and with so little disturbance in every way that the good mother observed that the case did not amount to much, and held it to be a much less serious matter than her own case of ankylosis of the elbow (non-operative) which had slowly yielded to treatment. Five thousand dollars would really have been a fair charge in the case, and the mother would not have hesitated much about paying that amount for an automobile or for a small pearl necklace. Please do not consider that I am making claim for skill beyond that of very many of us who have made sacrifices and have given ourselves opportunities that are to-day available in many fields of practice. During the year I turn over to other surgeons thousands of dollars worth of work in special cases that they will manage better, although I have taken trips to Europe and have gone to great expense in order to try and become proficient in these very cases. Things have changed since the days when the kindest hands did the wrong things for patients, and that was not so very long ago. One of our naturalists told me that he planned to write a book on insects injurious to orchard trees. At the end of a year he found that it would be necessary to devote himself to scale insects alone; and subsequently he devoted himself to one genus of scale insects, and filled a book with the available knowledge on about three hundred species of this one genus. Precisely the same thing applies to special work in medicine and in surgery to-day.

New York, July 5, 1905.

Dear Doctor Morris:

I have been considering the amount of your bill, which you sent me twice within the month, and after consultation with friends who have had similar service rendered by Dr. A., and by Dr. B., for much more *serious* matters, it seems to me that the basis established by Doctors A. and B. should be satisfactory to you, and therefore hand you my cheque for $600.

Sincerely yours,
Mrs. C.

New York, Sept. 23, 1905.

Dear Mrs. C.:

Your letter and cheque for six hundred dollars came while I was entirely out of reach of mail, and my secretary informs me that no answer was sent, because it seemed to be a matter requiring my personal answer. Now in regard to the points, *seriatim*. It is pretty well known that I do not undertake the responsibilities of any abdominal operation for less than one thousand dollars, excepting where there is need for doing otherwise, and in cases like your son's it has sometimes been several times that amount. The case was one of gangrenous appendicitis, with impending disaster; and the fact that the operation was done in twelve minutes, and our patient well in a few days, does not mean that I consider the responsibility as having been small. Some years ago I might have spent about an hour at the operation, and there might have been a hernia and other complications, following a tedious convalescence—if we had the fortune to get even that far.

In regard to Dr. A., people are very fortunate when they can really engage his personal interest and get his skilled services for his trifling fees. He is the last one of the noted surgeons here who adheres to the fees that were customary in the days when services were not worth quite so much as they are to-day, and we allow many cases to go to him every year rather than charge what we consider to be undignified fees. Dr. A. should ordinarily charge from five to ten times as much as he does; for standing at the head of the profession it would not only be his due, but would allow him more time for giving personal attention to cases that must often be turned over to assistants. Concerning Dr. B., his services consisted in successful treatment of an ankylosis of the elbow, if I remember correctly, and while this may seem to you to have been a "much more serious matter," it was really not in the same class at all. Even had I been so successful as Dr. B. was in that particular sort of case, my charge would probably have been less than the three hundred dollars. Dr. B.'s charge in a case like your son's might have been more than mine; and I consider that the charge of one thousand dollars for the operation, and eighty dollars for time, was a very moderate and friendly sort of charge. I shall not press the matter of collection of the balance of the bill, for it destroys the nice feeling of interest in the case itself; but I doubt if people generally know how surgeons feel about their patients who have been taken out of dangerous positions by accurate methods. If on further inquiry you happen to learn that my charge to you was less than my charge to others for similar work, I would be glad to know that, for it would relieve me from the feeling that you believe an overcharge to have been made. I do not know what charge Dr. D. (the family physician) made for his services, but in a case of this sort he would be entitled to special consideration on the ground of his prompt diagnosis and speedy action at a moment that was vital, and yet when many physicians would have hesitated, fearing to incur the displeasure of a family suddenly presented with the question of an unanticipated surgical operation of grave character.

New York, September 29, 1905.

Dear Doctor Morris:

I have just returned to find your note. I don't at all remember exactly what I wrote you last July, but at the risk of repeating myself I will mention what I think should be taken into consideration, in reflecting about the case. The fee for out-of-town work is, I know, a largely increased one, but I think on this occasion the work could hardly be put in that category. Because, if you remember, we telephoned you from my house in ——— —— at nine o'clock in the morning, asking you to come at once, and you replied that it would not be possible as you had three other operations for that day, and could only manage a late afternoon train. This you did, and returned to town before dinner. Thus it seems your trip of twenty miles out could not have interfered to the detriment either of your working day or with your dinner, or other working engagements. I believe the customary fee in New York with subsequent attendance is $500.00, so I sent you my cheque for $600.00, thinking $100.00 was not out of the way as compensation for that horrid little journey by ferry and train. I hope, dear Doctor Morris, that you will not think I am given to contesting my bills. I never have done such a thing, but I really felt that your secretary in the ordinary routine of work, had sent a memorandum that had not been looked over by you, who had full knowledge of the circumstances.

Sincerely yours,
Mrs. C.

A letter followed from me to Mrs. C., saying that I had added only eighty dollars for four hours' time, for the out-of-town part of the work, and that her letter was so frank and genuine, and represented such a common attitude of misunderstanding that I intended to refer the first part of the correspondence to three other surgeons for an expression of opinion, and for publication in a representative medical journal. Following are the letters of these three surgeons.

——— October 15, 1905.

Dear Doctor Morris:

I am very much interested in your letter of September 23, which I find on my return from my vacation. It is curious—Dr. F. and I, during our recent visit to Europe, spoke many times of the influence which Dr. A.'s fees are having in our community. I have the highest personal regard for Dr. A., and the greatest respect for his opinions and operative skill. I have told him that in my opinion he puts too low a value upon his services. Here in ———, when we charge people of large means what we think to be reasonable fees for the great responsibilities of surgery, we are told that men of great reputation in other large cities charge small fees. This makes it very difficult indeed to charge a fee at all proportionate to the responsibilities of the work. What other men do would not influence me in the least. I know that we are inadequately paid for the responsibilities of the work. With reference to your particular case, it seems to me that the fee was none too large. One who has been all through the dreadful experiences of appendicitis, and who has seen the magnificent results of operation in skilled hands, wonders how a patient can write such a letter as this patient wrote you. I had one of my own children operated upon, and if I had been a wealthy man I should not have considered any sum too great to pay—even five thousand or ten thousand dollars. I know what it means to open the abdomen. It may mean a brilliant recovery or it may mean an early and distressing death. I know what it means to have the intimate knowledge of acute abdominal conditions which enables a skillful surgeon to ward off impending disaster, and I know what it means when the blow is unskillfully parried. Your patient is mistaken about Dr. B.'s fees in abdominal work. However annoying to the patient operation on the elbow may be, it does not involve possibilities of early death. In all abdominal cases I charge a thousand dollars for operation, and in some cases I charge more. When I charge more than a thousand dollars I tell patients why I make the charge. It is always because the responsibilities are heavy. In cases of patients of moderate circumstances my fee is diminished accordingly—much of my work is done for nothing. Your letter to this patient excites my admiration. I should like to be able to write in such a manner to one who had written me such a—what shall I say?—well, unappreciative letter—to put it in the mildest form.

Yours very truly,
E.

——— October 17, 1905.

Dear Doctor Morris:—It seems to me your bill was a very small one indeed for the services rendered. I feel as you do. Where people are abundantly able to reward the surgeon in some slight measure in proportion to his services, it is better to let them go elsewhere, rather than make trifling charges. Why do you not send a copy of your letter to Dr. A.? Send some of your people to ——— and I will train them for you.

Faithfully yours,
F.

——— November 10, 1905.

Dear Doctor Morris:

I have just returned from a vacation and find your letter. In reply would say that your fee for the services under the conditions appears to me to have been a reasonable one. Indeed, I was about to say, very moderate. All lives are equally valuable to the individual. On that basis the medical profession has always given its best skill without reserve and without compensation to those who were in need. The modern methods of surgery involve an enormously increased range of knowledge, an increased risk of error on account of the prompt and forceful action, which in itself is an element of danger to the patient's life, if improperly used; and therefore an additional individual responsibility. The revenue of the medical profession has not increased at all in proportion to the revenue of the lawyer, the artist, or the artisan. Living conditions have entirely changed. The surgeon, when a barber, could live on a modest compensation. The surgeon, as an educated man of taste and refinement, of social standing—and such refinement and social standing are necessary for maintaining his position and influence in the community—has entailed upon him an enormous expense. Formerly an uncouth man might go in and do the bone setting Now such a man would not be accepted or tolerated in the surgical field; and if he were, he would be the source of greatest danger to the patient, and expensive at any price. Again in the case of a well-known individual in the community, needing a surgical operation which carries elements of danger, not only from the operation but from the original disease, if the operation terminates fatally, the surgeon is criticised, justly or unjustly, and must bear the financial loss consequent upon the public knowledge that he "lost" that patient. For such people a larger fee must be charged if they can afford it. The skillful worker who recognized conditions, thereby securing good results with diminished hazard to the patient, deserves a large compensation because of the insurance against fatality that goes with his skill. Superior skill and superior judgment, not only demand but command superior fees.

Yours truly,
G.

———, Tuesday.

Dear Doctor Morris:

I enclose you a cheque for the balance of your fee, which you assure me is the customary one. My discussion with you has been a friendly one, and so you will not, I am sure, suspect me of any acrimony when I say that my feeling about the present excessive charge of surgeons is a very general one, and the reflection of a sentiment that is everywhere one of surprise and dissatisfaction. We do not question your ability, but we feel you make us pay too dear for it.

Sincerely yours,
Mrs. C.

New York, Nov. 9, 1905.

Dear Mrs. C.:

Thank you for the cheque for the balance of the bill, and also for the frank expression of opinion, with its true ring. Indeed I am only too familiar with the "feeling about the present excessive charges of surgeons, and the expressions of surprise and dissatisfaction." People feel that they are overcharged, and surgeons feel that they are underpaid. This sort of thing will right itself along normal lines, and in a few years we are likely to hear of large bills paid willingly by patients who know exactly the reasons for the bills. Surgeons would pay to each other very much larger fees than they at present dare to ask from their patients. Services may be obtained to-day which are immensely more valuable than any which could have been obtained a few years ago, but the people are not as yet awake to the fact. Curiously enough, the Jews, notably shrewd and particular in money matters, are as a class the first to adapt themselves to the new order of things, and to secure and pay for the last degree of technical skill on the part of medical or surgical experts. In New England there remains the most persistent tendency to feel that "almost anything will do," provided that charges are at a minimum. We are going through a transition stage in these matters at present, but the right is certain to prevail.

Yours truly,
R. T. M.

Robert T. Morris, M.D.,
616 Madison Ave.

DEATH BY ELECTRICITY.

To the Editor of the Medical Record:

Sir:—Your editorial on "Death by Electricity" in your issue of December 23 surprises me very much, especially the expression in your closing sentence: "And this raises again the question as to when death occurs in cases of so-called electrocution—whether it is while the subject is in the chair or while he is on the autopsy table." It is truly astonishing how quickly important facts are forgotten.

The question how electricity produces death in electrocution was very definitely settled by the report of a committee consisting of Prof. A. E. Kenneally and myself appointed by Governor Flower at the request of the Electrical World to investigate the subject. It was decided by that committee and so reported and published at the time that electricity, or at any rate, the alternating current employed for electrocution, caused death by producing rupture of the blood-vessels of the brain. There was at the autopsies marked evidence of such rupture and the microscopic investigation of the brain of the two subjects examined, viz.: the negro Hampton and Dr. Buchanan, showed abundant evidence of rupture of the vessels throughout the brain in verification of those observations on the autopsy table. These observations were repeated by other investigations subsequently at other electrocutions. The explanation of cerebral hemorrhage caused by electricity is to be found in the fact that the alternating current employed for electrocution causes violent contraction of all the muscular structure throughout the body, both the voluntary and the involuntary muscles, and hence the blood is driven forcibly into the brain and rupture of the overdistended vessels occurs in consequence. The absolutely bloodless condition of all parts of the body and the absence of blood in all of the vessels throughout the whole body below the head was noticeable at the autopsy, and when the cranium was opened it was found to be filled with blood. Up to the time of this investigation and the report of the committee, the cause of death by electricity was involved in obscurity and there was much speculation thereon. But that report settled the question as far as electrocution is concerned.

It is very well and proper to attempt resuscitation of those accidentally shocked by electricity, for in many instances they may be revived if the effort is made promptly and judiciously, but in these cases of accidental shock the condition is very different. The total energy of the current actually directed against the body is indefinite and uncertain and may be insufficient to cause death, but in the case of electrocution the strength of the current employed is definitely known, and it is applied in a manner to bring the whole body under its influence. Death is therefore both positive and instantaneous, beyond a question of possible doubt. The maximum electrical energy employed for electrocution is 1740 volts and 8 amperes: equivalent to 13,920 Watts, and since 746 Watts equals one horsepower, the energy used is equivalent to about 18 2-3 electrical horsepower.

Augustin H. Goelet, M.D.

New York.

Progress of Medical Science.

New York Medical Journal, December 30, 1905.

Typhoid Fever in Infants.—S. D. Williamson refers to a small epidemic of typhoid occurring in his community, the cause being an infected milk supply. Among the cases coming under the author's personal observation was that of a bottle-fed baby five months old, whose blood gave on the twelfth day a positive Widal reaction. The temperature curve was atypical only in that there occurred a morning remission of three and sometimes four degrees during the second week. The patient recovered.

Neurasthenia Among Blondes in the Southwest.—V. E. Watkins calls attention to the nervousness observable among women in the southwestern portions of the country. Most of the towns of this section are about four thousand feet above sea level and all physical ailments are popularly attributed to the altitude. Newcomers to the region generally experience a decided exhilaration. In those of dark complexion, this generally continues as a mere sense of well-being. In another class, however, this bienaise is followed by an abnormal excitation of the nervous system and later by more or less nerve exhaustion. In the author's experience nearly all of this latter class of patients were of light complexion—decided blondes. Men were less affected than women. Blondes who permanently reside in the section find that a trip East annually is of decided advantage to their general health. The manifestations of the trouble are various. It may be only a slight lack of self-control or may run on to a profound nervous depression. In nearly all patients there is an irritability of temper and inconsistencies of character associated with a beginning neurasthenia. An unaccountable drowsiness is sometimes complained of. Occasionally there is loss of weight without any appreciable cause. Menstrual disorders are frequent, particularly menorrhagia and metrorrhagia of functional type, and two cases are recalled of women who were obliged to make periodical trips East on account of this condition. Headaches are very common. Physical exhaustion is often the most prominent complaint, and inquiry soon showed it to be resultant upon an unnatural nervous energy prompting the individual to overexertion and bodily fatigue. Brunettes are seldom, if ever, affected.

The Recognition of Eyestrain by the General Practitioner.—C. P. Franklin asserts that the common indifference of many so-called neurasthenic patients to out-door sports and open-air occupations and their devotion to close work and in-door employments is due to eyestrain under the form of myopia because of the blurring of vision beyond the far point. On the other hand the distaste for close work shown by headaches, the narrowing of the palpebral fissure to shut out the aberrant rays of light and the blurring of the close point, may come from astigmatism, and symptoms arising from this state may and often do exert a decidedly deleterious effect on the general state of health. General diseases often cause ocular disturbances as does also the convalescence from many of the continued fevers. As an aid to diagnosis it may be noted that the patient suffering from eyestrain nearly always complains of symptoms related to the sight-blurring vision on close work or even diplopia, a mistiness after use of the eyes, smarting, burning lids, much distress after attending church, the theater, shopping, or any place of assemblage, and particularly during and immediately after traveling. Two further subjective symptoms of eyestrain are photophobia and muscæ volitantes. The obscure dyspepsias, the unrelieved headaches, the unclassified neurasthenias, the puzzling nasal reflexes, the perplexing dental symptoms, are often and only too often due to ocular conditions unrecognized by the general practitioner, not by any means through any lack of ability upon his part, but simply because the immense demands upon his attention to keep abreast of the time in his own department forbid his becoming familiar with conditions of the eye which are naturally a routine matter to the opthalmologist.

Medical News, December 30, 1905.

Thiosinamine in the Treatment of Tinnitus Aurium.—Personal experiences are given by S. McCullagh, who states that this remedy, also known as allylsulphocaramide, was first used by Hebra in 1892 for lupus. It is made by mixing 2 parts of the oil of black mustard, 1 part of absolute alcohol, and 7 parts of water of ammonia, warming for a few hours on a water bath at a temperature of 104° F., and then evaporating to dryness. The odors of mustard and ammonia are driven off, and, on cooling, glistening, white, acicular crystals of thiosinamine are deposited. It has a slightly bitter taste and a garlicky odor. It is sparingly soluble in cold water, soluble in 2 parts of warm water, and freely so in alcohol and ether. Internally the remedy produces a slight tonic effect and sometimes a diuresis. Occasionally a disturbance of the gastroenteric tract is noticed. Locally it appears to destroy newly formed connective tissue. The internal dose is from one-half to three grains, three times a day. For the relief of the special symptom noted in the title of the paper, the author has given the remedy in 38 cases. Of this number 20 patients were cured, 7 much improved, 5 improved, and 6 not improved. His general conclusions are as follows: (1) This drug exerts a markedly beneficial action on ear disease accompanied by the formation of new connective tissue; (2) this beneficial action is due to an increased pliability of the tissue, allowing the usual forms of treatment to accomplish their object better; (3) its administration should always be accompanied by mechanical measures; (4) as good results may be obtained by administration by the mouth as hypodermically; (5) better and more prompt results may be obtained in recent cases; (6) it exerts a beneficial action on vertigo; (7) care should be used in looking for contraindications; (8) better results may be obtained with it in the relief of tinnitus than with any drug used heretofore.

Some Observations on Leucoderma (Addison's Keloid).—F. Robbins gives a general description of this malady and records his personal experience with four cases. He inclines to the belief that the malady is dependent upon peripheral nutritive changes, probably due to a toxin introduced from without. Perhaps this toxin is

absorbed by the peripheral nerve endings and transmitted to those ganglionic nerve cells for which it has a special affinity and in which a degenerative process is sure to follow. The remarkable resemblance to the blotches of old vaccination marks is suggestive. Remedies which have proven of value are applications of copper sulphate in vaseline (20 grains to the ounce), glacial acetic acid, iodides internally and general hygienic measures. One of the author's patients presented the usual signs of pseudoleukemia with the usual blood changes. He has, however, no conclusions to present in deciding how for the blood extravasations which have been observed in the leukemias conjointly with changes in the vessels predispose to the development of what is considered as a trophoneurosis in general and as Addison's keloid in particular.

American Medicine, December 30, 1905

The Unconscious Value of Careful Clinical Examination of Patients.—Louis Faugères Bishop emphasizes the fact that the careful clinical examination of a patient, carried on while the judgment is suspended, gives the opportunity for the subconscious development of a valuable judgment. This is entirely lost when the investigation is curtailed in time or details, and when the premature judgment is allowed to be formed. Therefore it is most important that in every case in which we seriously undertake the treatment, to make a very complete investigation into the history, the physical signs, and the laboratory findings, and only after collecting these, to form judgments as to the best course of treatment for that particular patient. The physician who is to give the opinion should, as far as possible keep his mind free from conclusions until his final opinion is given upon the case. It is the subconscious mental activity that produces those results that are considered so valuable in all professional work.

Transplantation of Veins and Organs.—Alexis Carrel and C. G. Guthrie obtained the reversal of the circulation in the jugular vein, in the carotid artery, in the arteries and veins of a limb. Important anatomic changes of a transplated venous wall soon occur under the stimulus of the increased pressure. The thigh of a dog was completely amputated and afterward replanted by suturing the vessels, the nerves, the bones, the muscles, the aponeuroses and the skin. The pulsations of the popliteal and the posterior tibeal arteries immediately became normal, and the femoral vein filled with dark blood. A kidney was extirpated and transplanted by anastomosis of the renal artery to the carotid artery, of the renal vein to the jugular, and the ureter was made to open into the lumen of the esophagus. On the third day after the operation the kidney was directly examined. Its circulation was found normal. A good excretion of urine was going on. The thyroid gland was extirpated and replanted with reversal of the circulation. On the ninety-fourth day after the operation, the gland was found to have a good circulation.

A Plea for the Convict Insane.—Horace Phillips shows that penal institutions do not afford facilities for the care of the convict insane. In such cases trained attendants and skillful treatment are necessary. The care of many such convicts in an institution which was never intended for such a purpose, seriously damages the mental state of these convicts. Further, the rude and offensive remarks of persons concerning the condition of this unfortunate class, aggravates the morbid and sensitive nature peculiar to the insane. Pennsylvania is not upholding its reputation for progress and humanity, in failing to provide suitable accommodation for the care and treatment of this unfortunate class.

Indications and Contraindications to the Use of the Obstetric Forceps.—J. Thompson Schell, in discussing the indications for the use of the forceps, says that the disproportion between the expulsion force and the pelvic resistance is the chief and most frequent indication, and that a certain amount of experience with a good deal of common sense is necessary to be always able correctly to pick the proper time for its application. As to the contraindications in cases of hydrocephalic or macerated heads, the forceps is very likely to slip, and the cases can better be managed by a perforator and the use of the cephalotribe. A head freely movable at the brim should not be considered as calling for the use of the forceps, as version is the first operation.

Journal of the American Medical Association, December 30, 1905.

Counting Blood Platelets.—J. H. Pratt criticises the methods used by other investigators for counting blood platelets, and points out four chief sources of error which he thinks have vitiated their results: 1. Mistaking fragments of erythrocytes for blood platelets 2. The use of a graduated pipette, disregarding the tendency of blood platelets to adhere to glass. 3. The use of the ordinary counting chamber, preventing the employment of a sufficiently high power. 4. The lack of satisfactory preserving fluid. He describes his own method, using the following preservative solution: Sodium metaphosphate, 2 grams; sodium chloride, 0.9 gram; distilled water, 100 c.c. This keeps indefinitely, unless molds or bacteria develop. The other sources of error are avoided by special methods of cleaning the glassware, using a very shallow counting chamber and thin cover slip, etc. A comparative count by his own and several of the other methods is given.

The Diameters of the Normal and the Phthisical Chest.—From a study of the chest measurements of 502 normal individuals and in 54 tuberculous cases, using bony landmarks for locating the length and diameters of the chest, W. A. Bessesen deduces in substance the following conclusions: 1. The use of bony landmarks for locating chest diameters is accurate and easily applied. 2. The use of median values for evaluating anthropometric data saves time and the results are more accurate than the arithmetical average. 3. Important points in the shape of the chest, as well as the movements and capacity may be appreciated by observation of its principal diameters. 4. The development of the human chest passes through various stages from the deep or dorsoventral to the broad or transverse type. 5. In the fetus and young babe, the lower plane gives a greater depth and breadth than the mid-plane. 6. The fetus under 30 centimeters in length presents a dorsoventral type of chest—it is deep chested. 7. The new-born child represents the transitional type of chest—it is round chested. 8. During the first five years of life the most notable change is the rapid widening of the chest in its transverse diameter—it becomes broad chested. 9. At puberty the chest takes on an increase in length over the diameters—the adolescent becomes long chested. 10. From the eighteenth to the twenty-fifth year the development of the chest is fairly uniform in all its dimensions and represents the highest development—the broad long chest. 11 The dorsoventral diameter increases at an even rate from birth to maturity. 12. The phthisical chest of adult years, in general, shows an arrest in development of the transverse diameter following puberty. 13. The phthisical chest is a narrow one, tending to the rounded form, with a relative elongation. A number of tables are given with the text.

Myoma of the Esophagus.—J. Bryant, Jr., reports two cases of myoma of the esophagus, both in adults past middle life. In one of the cases there was marked stricture of the esophagus by the tumor which measured 3.2 by 3 by 2.5 cm., and there were also nodules and ulcers at the cardiac orifice and on the fundus of the stomach. In the other case there was no reported clinical symptom of stricture. Both cases were found in autopsies of patients dying from other causes and were the only instances of this tumor recorded in the autopsy records for five years of two large hospitals (the Boston City Hospital and the Long Island Hospital) and the Harvard Medical School. The apparent rarity of the condition, he thinks, warrants the publication of these reports.

Report of Committee on Proprietary Medicines.—O. T. Osborne and C. S. N. Hallberg report the work done by this committee during the last year. They refer to the work of the Council on Pharmacy and Chemistry, and call attention to the necessity for naming substances used in medicine according to some systematic plan. They state that while names must be formed for new substances or to designate newly discovered facts, in case of medicinal substances the names should at least have the origin or derivation for their basis. They also discuss the pharmaceutical nomenclature at some length.

Acute Hemorrhagic Pancreatitis.—C. F. New reports a case of acute hemorrhagic pancreatitis occurring in an insane woman aged 35. The attack began with nausea and vomiting, soon followed by severe epigastric pain and tenderness, requiring opiates, and followed later by fever, tympanitis, rigidity, and general jaundice. Death occurred suddenly within thirty-six hours from the onset of the disease. The autopsy revealed the pancreas, except a small portion of the head and tail, involved in a soggy mass of coagulated blood, together with lesions of the liver, kidneys, and spleen, an atheromatous condition of the larger arteries, and some fatty degeneration of the heart. The author discusses the symptoms and points out the difficulties of the diagnosis. The pancreas is seldom alone diseased, its functions can be more or less fully performed by other organs, or by a small intact remnant of its own tissues. Still, he says, there are some things that should arouse suspicion of its in-

volvement. Fitz has laid down a rule that when a previously healthy person or sufferer from indigestion is suddenly seized with violent pains in the epigastrium, followed by vomiting and collapse, and within twenty-four hours by a circumscribed epigastric swelling, tympanitis and resistance, with slight rise of temperature, one should suspect acute pancreatitis. The crystals described by Cammadge are also claimed to be pathognomonic. The only practical treatment is surgical.

The Lancet, December 16, 1905.

Some Investigations of the Nervous Manifestations of Rheumatism.—F. J. Poynton and A. Paine consider in this article the relations from the standpoint of rheumatism of chorea and meningitis. They first discuss the etiology of acute rheumatism, reiterating their well-known views on its bacteriology. The diplococcus which they accept has certain peculiarities. It is smaller than the streptococcus pyogenes, and causes physiologically an early production of acid and a greater production than the S. pyogenes. Experimentally they find that rabbits are more resistant, and arthritis and endocarditis more constant. It is difficult to raise the virulence. Summarizing, they say that they believe there is a great infective process, the rheumatic, to be placed among that series of infective processes in which the staphylococcus, streptococcus, pneumococcus, and gonococcus are to be found, and that the infective agent is a diplococcus, with, in all probability, some peculiar characters. They incline to the belief that rheumatic chorea is a local infection of the nervous system and that most of its symptoms are the result of a slight meningoencephalitis, and possibly a meningomyelitis. Their reasons are as follows: (1) They have isolated and cultivated the diplococcus from the cerebrospinal fluid in four cases of fatal rheumatism, in three of which there was chorea at time of death. (2) They have produced twitching movements, arthritis, endocarditis, and pericarditis by intravenous injection of the diplococcus into rabbits. (3) They have demonstrated the presence of diplococci three times in the cerebral pia, and once in the brain from chorea cases. (4) They have also demonstrated their presence in the brain and pia of the rabbit that showed the twitching movements. Concerning rheumatic meningitis their conclusions are less positive. They incline to the assumption of an acute rheumatic toxemia as contrasted to the multiple and local lesions of chorea. Between the two comes rheumatic meningitis. Hence, they suggest the following sequence: First, mild rheumatic carditis and chorea; second, severe rheumatic pericarditis and rheumatic meningitis; third, acute fatal rheumatic cardiac dilatation and acute fatal rheumatic hyperpyrexia.

The Treatment of Tuberculosis of the Urinary System by Tuberculin (T. R.)—The results of personal experience in twenty-one cases are given by J. G. Pardoe. Of this number five appear to have been cured. Bearing in mind, however, the tendency to relapse, the author prefers to call them only apparent cures. Fatal cases numbered six and in one the author admits that the injections undoubtedly caused death. Much improvement was noted in four cases and no improvement whatever in six. As to the selection of suitable cases for this remedy, much reliance must be placed on cystoscopic findings. If both ureteric orifices are swollen, inflamed, and in some cases surrounded by ulceration, the probability is that the ureters are also infected, whilst it is often possible to observe a flaky or even distinctly purulent efflux from one or both sides before changes have taken place in the orifices. T. R. should never be given unless there is a clear orifice and a clear discharge on one side at all events. If the cystoscope shows a bladder free from, or but slightly infected with, tubercle with strong evidence of a unilateral infection of one kidney and ureter, *i. e.* a clear and normal efflux from one side with a purulent efflux and an infected orifice on the other side—nephrectomy and ureterectomy, followed by the use of T. R., are indicated.

British Medical Journal, December 16, 1905.

Union of Severed Nose.—J. Murray Renton relates the history of this case. A young woman lost control of her bicycle and was thrown through a plate glass window. Twenty minutes later she was seen by the writer. The tip of her nose was missing and her upper lip was so gashed that it was attached to her face by the internal mucous membrane only. Ten minutes later the tip of the nose was found; it measured about three-quarters of an inch from side to side, half an inch vertically, and its thickness was under an eighth of an inch. It contained almost no cartilage. As it was quite cold, it was placed in warm water for a few minutes, was washed in lysol, 1 in 40, and was secured in position by four cat-gut stitches. The wound was then painted with the compound tincture of benzoin, a few shreds of cotton wool saturated with this liquid being then applied. The lip was treated in the same manner. The patient was put to bed and kept there for ten days; only liquid food was administered. She was able to feel the point of a pencil when touched to her nose within twenty-four hours. There was a gradual increase in the acuteness of sensation which, in about four days, became normal. The wound healed by first intention. Excepting a little redness at the junction of the tip with the nose, and a slight nick in the right nostril, the organ appears normal. The lip also healed by first intention.

Sudden Death and the Thymus Gland.—Edward Jessop was called suddenly to take charge of a child about eight months old. On his arrival he found the patient dead. The lips were slightly blue and on each cheek was a dusky patch, but the finger nails were normal and there was no other sign of asphyxia. Artificial respiration was begun and persisted in for twenty minutes, but without effect. The infant had been fed from the breast and had been put to bed apparently in perfect health. About fifteen minutes later it was dead. The previous history was negative. The child was always considered to be extremely healthy. It was always noticed to turn on its face to sleep and had a habit of throwing its head back when in its mother's arms. Autopsy showed nothing abnormal excepting the thymus gland. This consited of three lobes and occupied the entire space from the thyroid to the diaphragm. Its measurements were four inches in length, two and three-fourths inches across, and three-fourths of an inch thick, and it weighed two ounces. The trachea was full of half-digested milk. The enlarged thymus may have been the cause of the attitudes which the child assumed. Doubtless these were the positions in which the pressure of the thymus was least felt. In this case there was no flattening of the trachea or evidence of pressure post mortem. The writer declares that there appear to be no symptoms by which this condition can be diagnosed with any certainty during life.

Prognosis in Mental Diseases.—Robert Jones declares that even the most skillful physician ought to speak with caution in the matter of prognosis in mental diseases. No human intellect can anticipate the numberless influences either for good or for evil that may come into play in any case. From the study of various statistics it may be stated that the death-rate among the insane in institutions is greater among men than women. Insanity is a diseased state which shortens life. The insane as a class are marked by considerable physical inferiority and lowered vital resistance to disease. The chances of survival in general are at least six times less than if insanity had not occurred. Insanity is curable in inverse ratio to its duration, and if active and skillful treatment be given within the first month, more than seventy per cent. of the recoveries are sent out cured. After the first year only about ten per cent. recover, and so on, till after the fifth, recovery is exceptional. Summarizing certain statistics, thirty per cent. recover, a small per cent. of whom relapse; thirty-three per cent. die in the asylums within a definite, time, and about forty per cent. remain incurable and eventually die insane. There is doubtless some mental weakness always left after an attack of insanity, and there is no complete and permanent recovery. Most certainly, complete recovery is infrequent. Tuberculosis in its various forms has been credited as one of the most frequent forms of the actual causes of death in insanity. The cases most prone to this affection are those of the depressed type, and those of adolescent dementia. The writer stiongly insists that the tendency to phthisis indicates a degeneration of the consitution and so a lowered resistance to disease. Below the age of seven years, prognosis is absolutely bad, and the younger the patient the worse it is. Imbeciles have a better expectation of life than normal individuals, if cared for in institutions. There are certain signs in the course of mental disease which are favorable to recovery, one of which is normal sleep. Another favorable symptom is the return of facial innervation and the restoration of the natural expression and appearance, as is also the revival of natural affections. Defective habits, sometimes called "gatism," are bad prognostic symptoms. If the cause be a single powerful one, the prognosis is better than if several causes acted together. One cause acting for a short time is more favorable for the patient than a long-continued one. With an hereditary neurosis, recovery is quicker, and with an hereditary taint prognosis as to recovery is better.

Berliner klinische Wochenschrift. December 11, 1905.

Delivery of the Arm and Version.—Apfelstedt descants upon the difficulties often attending the release of an extended arm in performing extraction in breech presentations or after version. The additional time required to overcome this obstacle may be sufficient to rob an already partly asphyxiated child of its last chance of life, or the obstetrician may be placed in the difficult position of having to decide whether or not the danger to the child's life is sufficiently great to justify him in breaking the arm to effect its withdrawal from the uterus. The author believes that an efficient safeguard against the occurrence of this complication may be secured by a prophylactic preliminary extraction of the arm before the version proper. The hand, on entering the uterus, first seeks an arm and draws it down into the vagina, the version is then completed in the usual way, and the operator has the certainty that even should be second arm become extended its extraction will be much facilitated by the absence of the other member from the uterus. The active uterine pressure which after the rupture of the membranes renders it very difficult for any part of the fetus to reenter its cavity will, he avers, be sufficient to insure the arm's remaining in the vagina during the version. The author has made use of this procedure but once, though he found it of great value on this occasion.

The Relation of Toxin to Antitoxin Combinations.—Morganroth, as the result of experiments with cobra venom and antitoxin, comes to the following conclusions: By treating cobra hemolysin with dilute hydrochloric acid at moderate temperatures it may be converted into a modification which no longer possesses the faculty of combining with the antitoxin obtained by the injection of genuine cobra venom, though it may still combine with lecithin to form a lecithid. On neutralization of the acid the modification may return to its original form. This modification of the poison molecule also takes place when it is combined with the antitoxin. Consequently the addition of hydrochloric acid causes a dissociation of the originally stable toxin-antitoxin combination. If at the same time there are suitable quantities of lecithin present the toxin becomes free as a lecithid and thereby permanently loses the capacity of reacting with the antitoxin. In such solutions on neutralization of the acid the poison is found in active form in addition to the antitoxin. Even after the lapse of some time it is possible to recover in this way the poison as lecithid from neutral or over-neutralized mixtures of toxin and antitoxin. The quantitative recovery of the genuine poison may be simply effected by making use of the thermostability of the poison modification. By heating the acidified toxin-antitoxin mixture the separated antitoxin is destroyed, and after neutralization with alkali the total amount of poison with its specific properties may be demonstrated in the solution.

Münchener medizinische Wochenschrift, December 12, 1905.

The Roentgen Leucotoxin in the Blood in Lymphatic Leukemia.—Curschmann and Gaupp describe some experiments on the serum of a patient having lymphatic leukemia who was treated by means of the *x*-ray. Seven treatments were given in sixteen days and caused the leucocytes to decrease in number from 150,000 to 44,000 to the cubic millimeter. This diminution was almost entirely at the expense of the lymphocytes, for the polynuclear neutrophiles underwent a slight absolute increase. Serum obtained from the patient before the *x*-ray treatment was begun was injected into rabbits and found to be without significant effect on the number of leucocytes in their blood. Serum obtained after the seventh treatment, however, when injected into the animals in all instances caused a notable drop in the number of leucocytes, the effect usually being most pronounced from four to six hours after the injection. Serum inactivated by exposure to a temperature of 60° C. for half an hour did not exhibit this leucotoxic property. Experiments were also made *in vitro* by adding the leucotoxic serum to human leucocytes and evidence of the leucotoxic power of the serum was easily obtained. The authors conclude that through the action of the *x*-ray there is formed in the blood of leukemic patients a specific leucotoxin which has an elective action on the leucocytes in the circulating blood of animals, and on the normal human leucocytes *in vitro*. This serum may be inactivated by heating and then loses its leucotoxic properties. The injection of the leucotoxic serum causes an immediate leucopenia which lasts from one to one and a half hours and is probably of chemotactic nature, like that caused by the injection of any foreign serum. This is usually followed by an active hyperleucocytosis which is succeeded four or five hours after the injection by the specific *x*-ray hypoleucocytosis.

Sahli's Desmoid Reaction.—Kühn publishes a series of control observations undertaken to determine the accuracy of the procedure recently devised by Sahli for testing gastric efficiency without the use of the stomach tube. The techique of the method has been described in the Medical Record, May 20, 1905, page 779, December 23, 1905, page 1034, and December 30, 1905, page 1062. Kühn carried out the Sahli reaction in thirty-four cases in which a test breakfast was afterward given and the stomach contents analyzed in the usual way. The results were in each instance thoroughly satisfactory in corroborating the value of the new method, and the author accordingly considers it a reliable addition to the diagnostic procedures in gastric work. It is especially suitable for application by the practitioner on account of its simplicity and the slight inconvenience it causes to the patient.

Gärtner's Tonometer.—Raab considers that the criticisms which have recently been made of this instrument are without foundation, and that not only is it not open to the objections that have been brought against it, but it has the advantage of being the only instrument which makes it possible to measure the capillary pressure. He records a long series of comparative determinations made by means of the Riva-Rocci instrument which show that the Gärtner readings are consistently lower. The Riva-Rocci sphygmomanometer determines the pressure of the heart-aorta district, which is to a large extent dependent on the alterations in peripheral resistance caused by variations in the capillary tension. The author's conclusion is that it is therefore necessary, in order to obtain a satisfactory insight into the conditions of pressure existing throughout the circulatory system, to make observations with both instruments.

Deutsche medizinische Wochenschrift, December 14, 1905

Physiological Wound Treatment.—Esch reviews the considerations involved in the modern theories of inflammation and repair and especially those concerned in Bier's congestion method of treatment. These lead him to the conclusion that the abandonment of the old time antiseptic wet dressing in favor of the aseptic dry dressing was a mistake. It is now being recognized that the various phenomena attending the processes of inflammation are salutary in their purpose and that a rational method of treatment should encourage and not seek to prevent them. The congestion, edema, and assembling of leucocytes that are now known to be important steps in the resistance to infection and the process of repair are encouraged by the aseptic wet dressing. The allegation made against it that it macerates the tissues and furnishes a moist chamber for the development of bacteria is valid only when the dressing is improperly applied, by being too wet. Correctly used, through its congestive action it encourages the natural processes of healing to a greater degree than does the dry dressing, and it is also more effective in relieving the subjective symptoms of the patient.

The Surgical Treatment of Puerperal Pyemia.—Opitz in discussing the value of the ligation of the ovarian and internal iliac veins recently recommended by Bumm in the treatment of puerperal pyemia describes a case in which he employed the measure without benefit to the patient, who died of heart failure shortly after the operation. His procedure differed from that advocated by Bumm in that he excised portions of both ovarian veins but did not ligate the iliacs. So far nineteen cases have been reported in which Bumm's suggestion has been followed, with six recoveries. Inasmuch as Opitz has seen thirteen recoveries take place in eighteen cases in which no operation was done, he considers that discretion is necessary in establishing the indications for the intervention. Bumm recommends the operation especially for chronic pyemia, but he reports a successful case in a patient having acute pyemia. Opitz says that as it is not possible to determine beforehand whether or not a given case will live long enough to become chronic it is better to attempt the operation in those instances in which the prognosis seems unusually grave. Belonging to this class are cases of pyemia following abortion, particularly if criminal, the removal of retained portions of the placenta, and placenta previa. Under these conditions if the outlook seems unfavorable he would recommend resort to Bumm's operation. While Bumm's efforts in this direction have accomplished much in developing the surgical treatment of pyemia, it is not yet time to apply his plan indiscriminately.

Weil's Disease.—Knauth reports six cases of this unusual condition, of which the cardinal symptoms are intense jaundice, swelling of the spleen, and nephritis. The patients were all privates in an infantry regiment. The period of incubation varied between a few hours and

several days, and the source of infection in one instance was ascribed to the consumption of tainted meat, while in the other cases it could not be accounted for. The portal of entry for the infective agent in one case was thought to be through the tonsils, in the others the poison was probably taken into the system through the intestine. The sickness began with a single severe chill or chilly feelings, and muscular pains. The tongue was dry and coated, the temperature elevated, and the facies that of typhoid fever. Later on swelling of the spleen developed and was conspicuous from the third to the fifth day. The pulse was accelerated in proportion to the temperature, a useful differential point distinguishing the disease from typhoid. Jaundice was present in half of the cases, and the kidneys were involved in only two instances. The differential diagnosis includes acute articular rheumatism, influenza, meningitis, and especially typhoid. The prognosis is not invariably good; one of the author's cases ended fatally and in all of the others ten to twelve weeks elapsed before complete restoration to health was secured.

French and Italian Journals.

A Case of Acquired Generalized Telangiectasis in a House Painter.—Mosny and Malloizel report this case. Acquired generalized telangiectasis is exceptional. The writers have found only ten observations of this affection besides the one which they report. They declare that they do not attempt to explain the pathogeny, which is so obscure, of these vascular dilatations. The patient whose history is here reported was a man forty-seven years old. He was a house painter. One evening after dinner he became uncomfortable and suffered from a sensation of heat, especially in his face. At the same time there appeared over the entire subumbilical region a slight swelling and generalized redness; he experienced at the same time intense itching. The redness had disappeared by the next day. Some days later the patient noticed the first appearance of the telangiectasis which he described as developing in the places which he had scratched. From that time these spots had become more numerous and had spread over the anterior surface of the two thighs and the dorsal surface of the left foot. In the last five or six years the spots had not increased. He began to paint in 1869. He had had one clear attack of lead colic twelve years ago. There is no trace of syphilis. The infected region often itches, especially in warm weather. In cold weather the spots become violet in color. The writers have discovered nothing to explain the pathogeny of this curious affection. A cytological examination of the cerebrospinal liquid showed a very feeble lymphocytosis. This liquid was not entirely normal, but contained more albumin than that of an absolutely healthy person. This is an interesting observation. The writers add that in order to prove the reality of the existence of a lesion of the central nervous system, a lumbar puncture ought to be practised at the very time of the appearance of these cutaneous lesions.—*La Tribune Médicale,* November 11, 1905.

Treatment of Cancer of the Larynx.—Cheval speaks of the curative methods in cases of cancer of the larynx as ablation by the natural passages, ablation by thyrotomy, and ablation by partial or total laryngectomy. Among the palliative methods there are morcellation or excision of the fungus growths, tracheotomy—as low as possible—and gastrostomy. The last-three mentioned methods are indicated when the physician has to treat inanition or asphyxia. The laryngoscope admits of an early diagnosis. The writer reserves the palliative treatment for cases which are strictly inoperable. It is important that diagnosis be made early. However limited the extent of the growth may appear, the writer advises total laryngectomy with systematic ganglionic enucleation. However short life may be after laryngectomy, the patient prefers this period to nothing. The writer lays great stress on the importance of these examinations being made by a physician who is capable of using the laryngoscope skilfully.—*Bulletin de la Société Royale des Sciences Médicales et Naturelles de Bruxelles,* July, 1905.

Spontaneous Cure of Morphinomania.—Rochon declares that a large number of physicians have a tendency to see in a morphinomaniac an organism impregnated with the poison which habit has made necessary for its regular functions. They consequently think that this drug cannot be entirely suppressed at once without provoking organic troubles which are sometimes very serious. Rochon reports a number of cases of which the following is a good example: A young man, twenty-six years old, was employed as a clerk. When he was twenty-two years old he had fallen from a horse, after which he suffered from sciatica. His physician gave him injections of morphine to quiet the pain. The patient continued this practice, and finally found that he was not able to lessen the dose. Four years after the habit had become established he was called to the bedside of his dying father, who reproached him for being the cause of his death. In his remorse the young man made a vow to renounce morphine entirely. He made good his promise and felt no ill effects therefrom.—*Journal de Médecine de Paris,* November 21, 1905.

Flies and Cholera.—A. Chantemesse and F. Borel, in speaking of the prophylaxis of this disease, declare that no sick person should be allowed to enter the country. The same measures should be instituted on the frontier railway stations as in the ports. Every patient who arrives should be immediately isolated, and his effects as well as the compartment where he has been should be disinfected. In individual prophylaxis two principles should be observed: the microbe of cholera should not be allowed to enter the organism; but if in spite of all precautions it has found its way into the body it should not be allowed to manifest its presence. In order to attain the first end all food and drink should be carefully examined. Protection against flies should be instituted, especially if defective water closets are in the vicinity. The organism should be put in the best condition of resistance. Every cause capable of bringing on an intestinal trouble should be avoided. If one can preserve intestinal equilibrium he can overcome cholera even though he become infected with the microbe.—*Le Mois Scientifique,* November, 1905.

Radical Cure of Varicocele by the Process of Durante.—Orazio Schifone tells us that in varicocele the object of oeprations is to reestablish venous circulation, the cause of insufficient nutrition and consecutive atrophy of the gland, and to prevent the elongation of the spermatic cord and the descent of the testicle, conditions that are very favorable to the establishment of varicocele. Simple ligature of the ectasic veins has no practical value. Double ligature is insufficient and dangerous, there being a possibility of including the principal artery of the testicle. The method of Durante satisfies all the demands of the operation. He denudes the mass of the veins that are enlarged, assures himself of the relations to the cord and the spermatic artery, passes a catgut thread under a few veins of the pampiniform plexus and ties it. He then passes and repasses the thread among the enlarged veins, drawing up the thread so as to constrict them. The veins are thus suspended just below the inguinal ring. The veins that are least affected are left out of the suture to nourish the tissues. The author has operated on forty-five cases in this way, of which he gives the histories and the results. Recurrences of the trouble are prevented, there are no nutritive or functional disturbances of the gland, there is no fibrous induration left, the neuralgic pains resulting from the condition are relieved the size of the scrotum is lessened. The author has also made experiments on animals which show that by this method the circulation is reduced, but the arteries are not occluded, nor are there alterations of the nerves of the cord nor of the deferent canal.—*Il Policlinico,* November, 1905.

Staphylococcic Septicemia in Typhoid Fever in Children.—Emilio Meynier describes his researches in three cases of typhoid fever in children, in which there was a secondary infection with staphylococcus aureus. In one there was an accompanying pneumonia, in another the staphylococcus infection was concomitant with the typhoid fever, while in the third it followed it in time. Bacteriological examinations were made of the blood, urine pleural pus, etc. The Widal reaction was positive. The infection with staphylococcus may occur at any period in the course of typhoid fever, and its presence will account for the prolongation of the fever and for many relapses. The author considers the bacteriological examination of the blood of prime importance in typhoid; a primary or secondary septicemia may simulate typhoid fever; the reaction of Widal is of equal importance, but, failing this, bacteriological examination of the blood will settle the diagnosis. The abstraction of the small amount of blood necessary gives the child little disturbance, and is not to be considered in comparison with the important results to be obtained. The most careful disinfection of the skin and mucous membranes in the later stages of typhoid fever are of the utmost importance in preventing secondary infection. A germ endowed with slight virulence may become the source of severe infection.—*Rivista di Clinica Pediatrica,* November, 1905.

Spinal Analgesia in the Diagnosis and Treatment of Rectal Diseases.—Neugebauer has found that a greater degree of relaxation of the anal sphincters takes place under spinal anesthesia than when any other mode of narcosis is employed. This fact can very advantageously be utilized if rectal disorders are to be diagnosticated or treated, for the paresis of the muscular tissues greatly facilitates inspection and operation in the district adjoining the sphincters.—*Centralblatt für Chirurgie.*

Book Reviews.

TEXT-BOOK OF ANATOMY. Edited by D. J. CUNNINGHAM, F.R.S., M.D. (Edin. and Dubl.), D.Sc., LL.D. (Glasg. and St. And.), D.C.L. (Oxon.), Professor of Anatomy. University of Edinburgh. Second and thoroughly revised edition. Illustrated with 936 wood engravings from original drawings, many printed in colors. New York: William Wood & Co., 1905.

LIKE all other branches of medical knowledge, anatomy is undergoing a steady accretion in its subject matter, and it is therefore not surprising to find that this, the latest and most highly developed exposition of the science, is a volume of almost 1,400 pages. Both paper and binding are of such excellent quality, however, that the volume does not appear unwieldy, and it lies beautifully flat wherever opened. That a new edition of so extensive a work in a field already well occupied should become necessary in so short a time speaks highly for its intrinsic merits. In its present form it is somewhat enlarged, mainly by the addition of a considerable number of new illustrations. Of these the most important is a set of drawings of the bones, on which the origin and insertions of the muscles are depicted in red and blue respectively. Contrary to the usual custom, these figures are introduced in the descriptions of the muscles, where they properly belong, instead of appearing in the section on osteology, as is commonly the case. The editor states that the sections in which the chief changes and additions have been made are those on embryology, the joints, the muscles, the brain and spinal cord, the genitourinary organs, the lymphatics, and applied anatomy. He also chronicles the death of one of the contributors, Dr. Ambrose Birmingham, formerly Professor of Anatomy in Dublin, whose section on the digestive system has been revised by Dr. Cunningham himself. In the notice of the work appearing in these columns on its first issue its many excellencies of matter and form were pointed out, and there is nothing but further commendation to add to-day. It is in every respect a model, and no more satisfactory treatise on anatomy can be recommended, either for the undergraduate student or as a work of reference for the library shelf.

A TEXT-BOOK OF CLINICAL DIAGNOSIS. By Laboratory Methods. For the use of Students, Practitioners, and Laboratory Workers. By L. NAPOLEON BOSTON, A.M., M.D., Associate in Medicine and Director of the Clinical Laboratories at the Medico-Chirurgical College, Philadelphia. Second edition, revised and enlarged. Philadelphia and London: W. B. Saunders & Company, 1905.

THIS book is written by a teacher of clinical diagnosis who has learned by practical experience what the difficulties of the subject are and what are the needs of the student, and who has been able to meet these wants in a thoroughly satisfactory manner. The book is not one on diagnosis in general, but is rather a manual for the clinical laboratory worker. Special attention, the author states, has been given to outlining in progressive steps the various procedures in clinical technique, but in addition to the detailed description of the various methods of examination, the diagnostic significance of the clinical findings is given. In this second edition, issued only eight months after the first, there are no changes in the text, but a number of subjects are introduced or elaborated in an appendix. Among these are Biff's New Hemogelometer, Ficker's Reaction, the Leishman-Donovan Bodies, Ravold's Test for Albumin, Cammidge's Test for Glycerin, and Cipollino's Test. The subjects of cystodiagnosis and inoscopy are also given more extended consideration. As an example of the strides in the subject of clinical diagnosis which have been made in recent years, it is interesting to note that nearly one-quarter of the entire work is devoted to the blood.

FIFTY AND ONE TALES OF MODERN FAIRYLAND. By F. STRANGE KOLLE, M.D., Author of "The Grown Baby Book," "Pen Lyrics," etc. Illustrated by Flora Sheffield. New York: The Grafton Press, 1905.

THE little folks, for whom this volume is intended, will be delighted with the modern fairy tales here presented to them. We have submitted the book to the judgment and criticism of some eight or ten healthy children, and on the strength of their verdict of enthusiastic approval we feel safe in advising our readers of this recent addition to the small stock of fairy tales. Doubtless other juvenile critics will confirm the favorable opinion of our little friends; and the author is to be congratulated on having accomplished a most difficult task with rare skill.

TEXT-BOOK OF MATERIA MEDICA FOR NURSES. Compiled by LAVINA L. DOCK, Graduate of Bellevue Training School for Nurses. Fourth Edition, revised and enlarged. New York and London: G. P. Putnam's Sons, 1905.

THIS volume has been brought up to date by the incorporation of such changes as were necessitated by the recent Pharmacopœia. In addition to materia medica proper the book contains information, well arranged and accessible, on poisons and their treatment, emetics, hypodermics, serum therapy, and mineral waters; there is a list of the more important new drugs, and a good index. It is well and concisely written, and can be commended to the nurse as a model text-book and a valuable guide. With a common sense which is far from common, the author omits the subject of therapeutics as not being a part of the nurse's study; she also reminds the nurse that it is not her business to prescribe for patients. This omission and advice are both to be commended.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; Assisted by H. R. M. LANDIS, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. December 1, 1905. Lea Brothers and Company: Philadelphia and New York.

THE present installment of Progressive Medicine contains articles on diseases of the digestive tract and allied organs, the liver, pancreas, and peritoneum, contributed by J. Dutton Steele; on genitourinary diseases by William T. Belfield; on diseases of the kidney, by John Rose Bradford; Joseph C. Bloodgood writes on anesthetics, fractures, dislocations, amputations, surgery of the extremities, and orthopedics; and H. R. M. Landis has a section on practical therapeutics. The most lengthy contributions are those of Drs. Steele and Bloodgood; but all are valuable and, as usual, are clearly and ably written and easy to read. The criticisms supplied by the various writers are often as valuable as the résumés of the papers under discussion. The present number is well up to the high standard that the editors of this quarterly have taught us to expect.

ANATOMY AND PHYSIOLOGY FOR NURSES. By LEROY LEWIS, M.D., Surgeon to and Lecturer on Anatomy and Physiology for Nurses at the Lewis Hospital, Bay City, Michigan. Illustrated. Philadelphia and London: W. B. Saunders and Company, 1905.

THIS book owes its existence to the request of those whom the author has instructed in Anatomy and Physiology during the last few years. It contains chapters on osteology, the muscular, circulatory, respiratory, digestive, excretory, nervous, and glandular systems, the membranes of the body, the organs of special senses, the female organs of generation, and a final chapter on repair and waste, nutrition, animal heat, perspiration, and the power that supports and preserves health. Thus, the ground is covered pretty thoroughly; and though there is room for considerable difference of opinion as to how much anatomy and physiology a nurse should be expected to learn, we have no fault to find with the author on the score of quantity. But with the quality of the work we are not so pleased; in many places the book is indefinite and inaccurate. For example, the author teaches that all nerves take their origin in the medulla and the spinal cord; that the great sciatic nerve supplies the internal and external organs of generation; that the expired air has lost its oxygen; a "second hypoglossal nerve" is mentioned; there is some confusion in the use of the terms arm and forearm. These are only a few of the places where revision is necessary before the book can be recommended to nurses.

TEXT-BOOK OF MEDICAL AND PHARMACEUTICAL CHEMISTRY. By ELIAS H. BARTLEY, B.S., M.D., PH.G., Sixth Edition thoroughly revised with illustrations. Philadelphia: P. Blakiston's Son and Co., 1905.

THE announced aim of the author in offering a new revision of this book is to bring it abreast of the times, to present the various subjects in accordance with established facts and theories. This is a difficult task for a work on physics and medical or physiological chemistry will grow old in the making. Progress along these lines is no less astonishing than the reversion of theories as scientific investigation proceeds. And yet the author has acquitted himself with marked ability. From the older editions of Fowne and Atfield to this work is a mighty stride. The medical student will be really interested if not fascinated in the study of medical chemistry as here presented. It is not necessary to give a detailed review of the many features of this excellent work, from the introduction to a study of the urine which is a most notable and interesting résumé of what is known to date of this important subject. The student as well as the practitioner will do well to familiarize himself with the clinical significance of abnormal urine, for it is doubtless true that this aid to the diagnosis of disease is too little appreciated; many obscure troubles are easily and intelligently cleared up by a comprehensive knowledge of the clinical significance of abnormal urine. Suffice it say that the book can be profitably studied by both student and medical practitioner.

Society Reports.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Eighteenth Annual Meeting, Held in Louisville, Kentucky, December 12, 13 and 14, 1905.

Dr. Lewis C. Bosher, of Richmond, Va., President.

Surgical Repair of Injured Nerves.—Dr. J. Shelton Horsley of Richmond, Va., reviewed the work of recent investigators on the histological regeneration of nerves. He alluded to the views of Bethe, and others, who claim that regeneration of a peripheral nerve can take place without central connection. He classified the surgical methods of repair as follows: (1) Simple nerve suture, including all cases where the ends of the nerve are brought into direct contact and sutured, even when nerve stretching or resection of the long bone may be necessary. (2) Flap operations, which were usually unsatisfactory. (3) Nerve bridging. By this term was meant those cases in which a foreign substance was used to bridge over the defect between the ends of a divided nerve. This included not only transplantation of nerve tissue from lower animals, but also *suture à distance*. (4) Nerve implantation or anastomosis. Under this head were included those cases in which the ends of an injured nerve were implanted into a healthy nerve. He reported a case falling under the last classification. The patient had suffered an injury, as a result of which the upper part of the median nerve had been destroyed for two and a half inches and the musculospiral injured in the lower part of the arm, with paralysis of all muscles in the hand and forearm except those supplied by the ulnar. Three months after this the median was implanted laterally into the ulnar. Fourteen months later both flexion and extension had returned to a marked degree. At that time the musculospiral was cut across and implanted laterally into the median. Ten months after the second operation sensation and motion of the hand and forearm had almost completely returned. In discussing several points connected with the case, Dr. Horsley concluded that the extensors must have been supplied through the anterior interosseous branch of the median, because flexion and extension improved simultaneously, and because extension was not interfered with at the second operation, when the musculospiral was completely divided.

Dr. Charles H. Mayo of Rochester, Minn., said one question that interested him more especially was the difference in the ability of repair between sensory nerves and motor nerves, and combined sensory and motor nerves. For instance, about the head, where we had the purely motor and sensory nerves, it was almost impossible to keep a sensory nerve from uniting itself. It would grow for inches and repair itself; but a sensory nerve having peripheral impulses towards the center seemed to lack the power of regeneration like a motor nerve in which the impulse came from the center out. He had taken out the infraorbital, plugged the opening with silver, and for as many as seven years there was no return of sensation in that area, yet within a few months, after operating again, and removing the silver plug, the sensory nerve which had been lying dormant for this length of time would get out, hunt up a partner, so to speak, and go to work. In the case of the motor nerve of the arm, where there were sensory and motor nerves, we would get more rapid regeneration because of the peripheral impulses, and as the sensory nerve of the arm was so much in excess over that of the leg, we would get earlier repair in the surgery of nerves of the arm than we would in the leg.

Dr. Horsley, in closing the discussion, called attention to the point that his patient was of a low grade of intelligence, whose nervous system was not well developed, and the same law applied here as would apply to other similar cases, namely, the lower the type of organism, the more rapid and more active the repair.

Foreign Bodies in the Esophagus.—Dr. Stuart McGuire of Richmond, Va., said that the diagnosis of foreign body in the esophagus was based on the history of the case, the external palpation of the neck, the passage of an esophageal bougie, and finally by the use of the *x*- ray. The character and location of the foreign body being determined, the practical question was how to remove it. If it was round or smooth, efforts should be made to extract it with forceps and probangs, or to make the patient eject it by swallowing masses of partially masticated food and then vomiting. If it were small, it might seem wise to endeavor to push it into the stomach. None of these expedients should be tried when the foreign body was pointed, sharp, or angular. Under modern surgical technique, an open operation was the safest procedure. There were two means of approach, one by an external esophagotomy, the other by a gastrotomy, and the selection of the method would depend on the location of the impaction. If it was opposite the cricoid cartilage, an esophagotomy should be done; if it was below the level of the supraclavicular notch, then gastrotomy should be performed. As an illustration of the operations of esophagotomy and gastrotomy, he reported two cases. In one, the patient, aged ten, while playing with a glass stopper, put it in her mouth and swallowed it. It lodged in the esophagus opposite the cricoid cartilage and produced complete obstruction. The foreign body was removed by an external esophagotomy. The second case was that of a baby, aged seven months, who, while being dressed, seized an open safety-pin and put it in its mouth. The mother, in her efforts to remove it, pushed it first into the fauces and then into the esophagus. The pin was removed in this case by a gastrotomy.

Dr. J. Wesley Long of Greensboro, N. C., narrated the case of a forty-six-day-old infant who had swallowed an open safety-pin; the pin lodged in the esophagus opposite the two cricoid cartilages. A radiograph, however, showed that the point of the pin was below the arch of the aorta. It produced constriction of the esophagus where the left bronchus crosses it, and the pin was removed by an external esophagotomy without any shock. He thought there were some cases in which this operation was preferable to gastrotomy.

Dr. W. S. Goldsmith of Atlanta, Ga., mentioned the case of a patient who had swallowed the concave part of a dental plate, which lodged in the esophagus and was retained there for a period of four months. At the end of this time the patient was very much emaciated and weak. After locating the foreign body, efforts were made to extract it with forceps, but this could not be done. It then occurred to him to try Bull's method of attaching a series of sponges to a long silk ligature and this to an esophageal bougie. The latter was passed through the opening in the stomach and out through the mouth, leaving in position the series of sponges. It was then a simple matter by a few sweeping movements backward and forward to push the foreign body into the stomach and extract it through the gastrotomy opening. The foreign body was of such consistency that the *x*-ray was of no aid.
was of no aid.

Dr. H. A. Royster of Raleigh, N. C., reported the case of a child, two years of age, who, two weeks previously to his seeing the case, had swallowed the wheel of a tin toy wagon. The child was able to swallow liquids, but not solids. During this time it subsisted on milk and liquid food. He used a medium-sized, shotted, semi-elastic bougie for the purpose of an examination; this passed into the esophagus met with some resistance, after which he was enabled to pass it further without obstruction apparently. After applying a mouthgag he was enabled to extract the foreign body with an esophageal forceps. The foreign body lay transversely across the esophagus.

Dr. J. Shelton Horsley of Richmond, Va., said if a foreign body could not be removed by ordinary means, no time should be lost in resorting to early operation. He reported the case of a child who had swallowed a toy camel which lodged a little below the level of the larynx. He

tried to extract it by several different methods, but was unsuccessful. He saw the child on the fourth day after it had swallowed the foreign body, did an esophagotomy, and removed it with comparative ease. The esophagus was injured and gangrenous. Septic symptoms developed, and the child died on the fourth day following the removal of the foreign body. He thought the child's life might have been saved by an earlier operation.

Dr. Charles M. Rosser of Dallas, Texas, reported two case of foreign body in the esophagus. In one, the foreign body, an ordinary pin, was located by the *x*-ray, but could not be removed by ordinary means. Two-thirds of the pin was buried, but with the aid of the fluoroscope the pin was caught by its head, and extracted with forceps. In the other case, that of a child, a nickel was located within two or three inches of the cardiac end of the esophagus. Gastrotomy was performed, and the foreign body extracted. The child lived about six or eight hours, then died, apparently without shock.

Dr. Rufus B. Hall of Cincinnati, O., reported the case of a child of a physician, five months old, who swallowed a safety-pin an inch and a half long. It remained in the esophagus for a time, but at the end of twenty-four or thirty-six hours the symptoms caused by its presence disappeared. The child was able to take the breast and thrived well. An *x*-ray picture was taken which disclosed an open safety-pin in the pyloric end of the stomach. The parents declined an operation for its removal until unfavorable symptoms should develop. Severy *x*-ray pictures were taken, but the child did not develop any unfavorable symptoms referable to the presence of the safety-pin. When the child was twenty-six months old it passed the pin by the natural route. The child was now seven years of age.

Dr. W. D. Haggard of Nashville, Tenn., related the case of a child, eighteen months old, who swallowed a pin, the head of which was as large as a cherry-seed. The child developed cough, and the presumption was that the pin had lodged in a bronchus. An *x*-ray picture threw very little light in regard to the presence of the foreign body. The pin appeared to be in a bronchus, with its head down and to the left. The child had little or no pulmonary symptoms to justify an operation. At the end of ten days another *x*-ray picture was taken, but the symptoms were so slight that operation was deferred. Four days later another radiograph was taken, which failed to locate the pin, and shortly after this the child passed the pin by the natural route.

Dr. McGuire, in closing the discussion, said no hard-and-fast rules could be laid down as to whether esophagotomy or gastrotomy should be done in a given case. Of the two operations he preferred to do gastrotomy. It seemed easier and the after-treatment was simple. If it was equally applicable, it was the method to be adopted.

Gallstones in the Cystic Duct.—Dr. L. H. Dunning of Indianapolis, Ind., presented a method which he had employed in one case which greatly facilitated the pressing backward into the gall-bladder of a stone impacted in the cystic duct. In this case the gallstone was lodged in the cystic duct in front of a small stricture. After making all the efforts he deemed prudent to press the stone backwards into the gall-bladder without success, he then unsuccessfully attempted to dilate the stricture with the finger-tips and later with forceps. One of his assistants suggested that they could better dilate with the forceps if they could see the stricture. The walls of the gall-bladder were elastic. The liver had been turned upwards, so that the gall-bladder was near the surface. The opening in the gall-bladder through which he had been working was enlarged a little, and then the stone was steadied and held against the stricture by an assistant. The fundus of the gall-bladder was pushed forward toward the strictured entrance into the cystic duct. They so far succeeded as to bring the opening in the wall of the gall-bladder directly opposite to the strictured opening. They then tried to introduce the forceps tips, but failed. Picking up a pair of probe-pointed scissors curved on the flat, he gently worked the point through the fistula and opened the scissors; this did not dilate the opening sufficiently, so the edge of the fistulous ring was snipped slightly in two or three places, when they were able to dilate the fistula so as to permit the easy exit of the stone. The operation was completed in the usual way. A rubber tube was fastened in the gall-bladder and that viscus anchored to the fascia. Before they had finished the operation a little bile had flowed into the gall-bladder. Two or three ounces of bile was discharged from the tube daily; at first it was dark and thick, but gradually approached the normal color and consistency. The patient made an uneventful recovery, and had but little further pain or soreness in the gall-bladder region. He thought the procedure adopted in this case might be found of service in others. It was not applicable to cases in which the gall-bladder could not be brought near the surface, or where the gall-bladder was thickened by inflammatory deposits. In the author's experience in operating upon ninety-three cases of gallstones, there were ten cases of stone in the cystic duct requiring considerable effort to dislodge them. In two of the cases early in his experience the stones were crushed and portions left behind, subsequently giving so much trouble that cholecystectomy was finally performed.

Common Duct Obstruction.—Dr. J. Wesley Long of Greensboro, N. C., stated that, as compared with gallstones in the gall-bladder, this condition was many times more serious. He quoted the as yet unpublished statistics of the Mayo clinic, where there had been more gallstone operations done than in any other clinic in the world, showing that in simple gallstones in the gall-bladder the mortality of operation was less than one-half of one per cent., while the mortality in operations for common duct obstruction ranged from 11.9 per cent. in benign cases to 40 per cent. in malignant cases. These facts were brought out to emphasize the prophylactic value of operating while the stones were yet in the gall-bladder. Touching the etiology of common duct obstruction, he took the position that practically all cases were due either to stones or to malignant growths which themselves were caused by the irritating presence of stones. Gallstones might exist in the gall-bladder for a long while without producing symptoms, but once in the common duct, not only pronounced symptoms, but many serious complications arose. The mortality in these cases was due to the complications, the cholemia, infection, inflammation, and exhaustion from hemorrhage at the operation. He emphasized the fact that common duct obstruction could be treated only by surgical methods. After removal of the obstruction, the first consideration was drainage, since it was imperative to overcome the infection, and, second, that no operation must be deemed finished until the patency of the opening into the duodenum was assured. Attention was called to the importance of not removing the gall-bladder in the operation of choledochotomy, since stones occasionally reformed in the common duct and in these cases the gall-bladder served for drainage. A number of cases of operation for common duct obstruction occurring in the hands of Dr. Long were reported, showing the profound disturbance caused by the stones, and the great relief afforded by their removal. In one case it was noted that the stones had ulcerated through the side of the gall-bladder and into the common duct—an exceedingly rare occurrence.

Gangrene of the Gall-Bladder; Rupture of the Common Duct; a New Sign.—Dr. Joseph Ransohoff of Cincinnati, Ohio, reported a case of gangrene of the gall-bladder in a male patient, aged 21, with recovery following operation. The second case was one of rupture of the common duct with an unusual sign. Operation was done, followed by recovery of the patient. Although the cases differed in many important points, they had enough factors in common to warrant their consideration together. In each of them a rapidly developing peritonitis made an operation impera-

tive as a vital indication. In each the operation revealed a condition which to the naked eye at least had all the earmarks of a peritonitis, which might speedily cause death. In one there was an unruptured but gangrenous gall-bladder, the contents of which were proved to be sterile; in the other there were large quantities of free bile in the peritoneum. He called attention to a sign which was noticed in the case of ruptured duct before the incision was made, and one to which he believed attention had not been directed. It was a localized jaundice of the umbilicus. Although a single case was not usually sufficient to warrant the assumption that something new had been observed, this feature was so marked that he could not refrain from believing that further observation would give to this localized jaundice some value as a sign of free bile in the peritoneal cavity. In the case presented this feature gained in interest as the staining of the subperitoneal fat with bile was observed in the incision through the abdominal wall. The jaundice was doubtless purely the result of imbibition. It made itself manifest first in the integument of the navel, because this part was thinner than the rest of the abdominal wall. Total gangrene of the gall-bladder had, to his knowledge, not been observed, except in the case presented, as an affection independent of gall-stones. Total gangrene of the gall-bladder was rare. In the case reported a most careful search failed to reveal the presence of a stone.

Experience with Downes' Electrothermic Angiotribe in Pelvic and Abdominal Surgery.—Dr. J. Wesley Bovée of Washington, D. C., had employed these angiotribes in 203 abdominal and 27 vaginal operations These 230 operations had been hysterectomies and panhysterectomies, removal of the uterine appendages by the vaginal route, removal of the same structures by the abdominal route, removal of the vermiform appendix, the spleen, the kidney, parovarian cysts, portions of the intestines, etc. The instruments were described in detail; also the technique of application. In these 230 cases he had had two of hemorrhage subsequent to operation. He could not believe the method of hemostasis employed was responsible in either instance. In the first, abdominal panhysterectomy was done for severe suppurative inflammation of the appendages of a very feeble and emaciated woman. Three weeks later, after being allowed to walk about for two days, she was seized with hemorrhage from the bowels, stomach, and vagina. A mass was found in the pelvis; her temperature became elevated, as was the pulse rate. The hemorrhage continued at intervals for two weeks without improvement, and then the abdomen was reopened without any form of anesthesia, even local being refused by the patient. A large amount of blood coagula was removed from the peritoneal cavity, vaginoabdominal through-and-through rubber tube drainage was installed, and thorough irrigation of the peritoneal cavity, with salt solution, was done after separation of multiform adhesions. Later feces and urine escaped by both ends of the drainage tract. Persistent irrigation and feeding cured her malady and she was a robust woman to-day. In another, two weeks after vaginal hysterectomy for fibromata, the patient had a sharp vaginal hemorrhage after walking a little more than on previous days. An examination with a Sims speculum revealed a malodorous discharge from the left lateral fornix of the roof of the vagina. The temperature was elevated about one degree. Daily irrigation for a week ended the trouble. In both cases he was confident latent mild infection was responsible for the hemorrhage. In no other instance had hemorrhage occurred, and he had the simplest and most perfect faith in the hemostatic properties of the instrument. The advantage of the electrothermic angiotribe of Downes in pelvic and abdominal surgery seemed to be a more reliable hemostasis than by ligation; freedom from hemorrhage during operation; the ease of its application in locations in which the use of ligatures would be very difficult and uncertain; the greater security against dissemination in radical operations for malignant disease; the ability to sterilize unclean areas before suturing, as in intestinal and appendical surgery; lessening of the tendency to the formation of postoperative adhesions; the increased speed in operations, such as removal of the uterus, the appendages, or the vermiform appendix, and the greatly lessened amount of pain following operation. The disadvantages were the danger of accidental injury of the bladder, rectum, or ureter, the necessity of great precision in its employment, and the special care necessary to keep the paraphernalia in good working condition.

Dr. Andrew J. Downes of Philadelphia, in speaking of his instruments, stated that for four years he had not used a ligature except in the case of a woman upon whom he operated for extrauterine pregnancy, and who was moribund at the time. He had performed intestinal anastomoses and gastroenterostomies with his instruments; other surgeons had removed gall-bladders, kidneys, etc. Personally, he had done four or five hundred hysterectomies with them, while other surgeons had performed from sixty to seventy hysterectomies with them. He did not think hemorrhage in the two cases reported by Dr. Bovée could be attributed to the use of his method.

Dr. Charles P. Noble of Philadelphia had used the Downes instruments a number of times in cases of removal of the uterus for cancer, and said they were a great advance in this operation. They possessed a number of advantages over the application of the ligature. The chief advantage of the clamps over the ligature was that after the uterine arteries were tied on each side, when one came down to the vaginal plexus, which was the most troublesome part of the operation when using the ligature, the veins were apt to leak and flood the field, requiring a number of ligatures to secure hemostasis around the cut vagina. If these instruments were used, the field would be perfectly dry. There was no trouble from hemorrhage. From the standpoint of recurrence of cancer, the instruments had not been used long enough to give figures as to results; but one could believe from the work of Byrne that much better results could be obtained with the aid of these instruments than with ligatures, etc.

Dr. Howard A. Kelly of Baltimore said he saw Keith of Edinburgh, in 1887, remove an ovarian tumor with Skene's instruments; but those instruments were not satisfactory, and when Dr. Downes brought out his instruments he procured a set of them and had found them of service, with the exception that he had not been able as yet to install a satisfactory plant in the Johns Hopkins Hospital for their use. While the Downes instruments were practical and useful in surgical work, he thought if surgeons exercised more care as to the character of ligatures they used daily, it would limit the use of the Downes method of instrumentation. He referred to the importance of using fine silk ligatures which controlled bleeding from large blood-vessels and were practically innocuous.

Operation for Large Rectocele.—Dr. George H. Noble of Atlanta, Ga., presented the technique of an operation which was intended only for large rectocele. Small rectocele was relieved by the ordinary perineal operation. In operation for a large rectocele not infrequently there were more or less tediousness, loss of blood in the denudation, and certain objections to puckering the overstretched and distended tissues together and forcing them into the rectum. Furthermore, there were unsatisfactory results by infecting the strong and resisting rectovaginal septum. This operation was presented for the purpose of overcoming those objections. In the technique it would be observed that the rectocele was actually resected, and that the strong or normal rectovaginal septum above the weak occluding point was drawn down to the level of the levator ani muscle and securely anchored. (1) A thorough dilatation of the anus and recleansing of the rectum. (2) Denudation of a wide collar, as it were, the ring around the neck of the rectocele, beginning high up in the vagina and extending

near to the promontory of the rectocele. It was unnecessary to remove the mucosa over the last point mentioned, as it was cut away in the resection. By proceeding with the denudation from within outward, the veins of the recto-vaginal septum were cut through at a high point and secured with compression forceps, and the necessity of repeatedly cutting the same vessels in the process of repairing the wound was avoided. (3) Two fingers were placed upon the promontory of the rectocele, carried into the vagina and out through the anus, forcing the rectocele ahead of them, and in this way completely everting it through the anus. It was seized with a pair of forceps at the point where it protruded and was gradually drawn down step by step until the lax portions were secured and a feeling of tenseness was felt. If in drawing the anterior rectal wall down the normal parts of the rectum did not come as low as the levator ani, the rectum should be liberated by dissecting it from the vagina, which would permit of further descent and allow all the overstretched tissues to project beyond the anus. (4) A light pair of compression forceps was then placed upon the neck of the rectocele just external to the anus for the purpose of holding it in position. (5) Two sutures, preferably medium sized kangaroo tendon, were passed through the unruptured portion of the perineum close to the sphincter ani muscle after the manner in which Emmet inserted his tension sutures in perineorrhaphy. These two sutures in passing across from side to side should take up the prolapsed portion of the anterior wall of the rectum. When tied, they closely approximated and anchored sound or healthy rectum to the levator ani muscle and rectal vessels in the deep pelvic fascia. (6) The vaginal side of the wound was completed by doing perineorrhaphy. The protruding rectocele was amputated about three-quarters to an inch external to the clamp, and its edges closely sutured with continuous suture of catgut. The case was treated then as an ordinary perineorrhaphy, except that a wet soft dressing was placed over the protruding stump. The stump retracted within the anus in a week's time, and took care of itself. The author reported five cases, in which he did this operation, with very satisfactory results.

Starvation and Locked Bowels for from Ten Days to Two Weeks.—Dr. Howard A. Kelly of Baltimore offered, for a more extended trial in other fields as well, a method of after-treatment which he had used in some fifteen cases for the most part in complete tears of the rectovaginal septum. The treatment consisted in two parts—first, a very limited diet for from ten to fifteen days; and second, the locking up of the bowels during this period. The food was limited to albumin and water, nothing being given the day following operation, and but one dram every three hours in the second day, and increasing this a dram each day until the patient was taking four drams every three hours. In this way the patient was fed in all, in a period of ten days, not quite three pints of albumin and absolutely no other food. One patient was continued for fifteen days on this diet and without evacuation. At least two very frail patients had been treated in this way. When the evacuation took place, two drams of licorice powder was given and in some cases an oil enema, and the passage was secured with the patient lying on her side so as to avoid any straining. In no cases were there any scybala, nor was there any difficulty with the evacuations. Dr. Kelly thought this starvation plan of treatment might have a wider range of utility in treating dyspeptics and cases of hysteria, as well as in all kinds of plastic operations on the intestinal tract.

(*To be continued.*)

Aluminum instruments should not be boiled in soda solution, like other instruments. They are to be sterilized by boiling in plain water or by passing them through an alcohol or Bunsen flame.—*American Journal of Surgery.*

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Ninety-ninth Regular Meeting, Held on December 1, 1905.

The President, Dr. T. Mitchell Prudden, in the Chair.

Exhibition of Patients and Casts of Cases Treated by Radium.—Dr. Robert Abbe presented eight patients and numerous colored casts of cases from many treated by him during the past two years to illustrate definite, tangible, and lasting results from radium treatment, often following a failure of the Roentgen rays. To show the scope of its usefulness, there were also shown cases of epithelioma, lupus, chronic warts, and submucous hyperthropic gland inflammations.

The first patient exhibited was a man, 45 years of age, who had had for five years a group of hot, burning and itching, red, lupus-like masses in the center of each cheek, about one inch in diameter, consisting of a conglomeration of tubercular and scaly, but not ulcerated nodules. These were so distressing that he frequently had to leave a hot room, or in summer go into the open air for relief. In addition to this, they caused much disfigurement. Five applications of strong radium in glass tubes were made at intervals of a week, for one-half hour or one hour each time, until a considerable radium inflammation was established, following which there was a rapid subsidence of thickness, leaving behind a healed, atrophic skin which had remained during the past year and a half without causing itching, redness, or burning. In other words, a radical and permanent cure had followed.

The second case was the larger of two cases of epithelioma of the ear reported in the Medical Record of August 27, 1904, which were cured by a few applications of radium, and had since then remained absolutely cured, with a fine, white and unnoticeable cicatrix. This cure had existed a year and a half.

The third patient was of the same type. The disease had existed eleven years, spreading from the upper rim of the ear, and had been operated on by the knife, with skin grafting, as well as by caustics and the curette until almost the upper half of the ear was gone. The disease had subsequently spread to the scalp and periosteum, and, excepting for short respites, it had been continually in evidence for eleven years. Two strong specimens of fifteen centigrammes of Curie radium (300,000) in thin glass tubes, were laid upon the sore for an hour five times during a single week. The sores improved in appearance within five days, and rapidly healed, so that in a month there were only two very small points left unhealed. These closed soon afterwards, and a soft cicatrix covered the entire cartilage, and had retained a normal, healthy appearance, as now shown, during the six months since it healed.

The fourth case was one of the same type of slow-growing epithelioma below the left nostril, which, during seven years, had enlarged until it had eaten away the ala nasi and part of the columna, and descended on the lower lip a full finger's-width until it involved the vermilion border. This entire surface was deeply ulcerated, and had thick, raised edges. A portion was taken for microscopic study, and found to be typical epithelial cancer (Dr. F. C. Wood). The patient was a woman of 75 years, and dreaded a surgical operation. The treatment consisted in laying upon the ulcerated surface several strong radium tubes. It was thus rayed for one hour at a time, seven times in ten days. Then a red zone of radium inflammation, a quarter of an inch wide, surrounded the disease, with no sensation to the patient, and retrograde changes showed in the growth. The raised margins began to flatten, and the foul red ulcer stopped secreting pus and was covered by a gray lymph. During the third week cicatrization had begun on all sides. During the fourth week all appearances of disease had disappeared, and a simple healing ulcer remained, of about a

third the original area. At the time of exhibition, the fifth week, the sore was nearly healed. (One week later, the patient returned to her home in a distant State with a healed sore and soft cicatrix.) In connection with this case, colored plates were shown to demonstrate the stages of healing. The treatment that had been previously resorted to in her case had been curetting, caustics, ointments, and the Roentgen ray. The latter had been given for many weeks by a competent man, with no apparent change. The specimens of radium used to cure this case were four in number, in glass tubes, as follows: Ten centigrammes (Curie), 300,000; five centigrammes (Curie), 300,000; twenty milligrammes (Curie), 200,000; ten milligrammes (German), 1,000,000.

The fifth patient shown was a remarkable case of sarcoma of the lower eyelid, who had been presented to the Society at a previous meeting when half cured. The tumor was a solid purple mass in the right lower eyelid, occupying more than half the entire breadth of the lid. It grew half an inch down the surface of the skin, and bulged well on the mucous membrane throughout its whole breadth. The ciliary edge was entirely lost in the mass, and no eyelashes grew from it. It had existed for a year, and had been under the close watch and careful study of Dr. Peter A. Callan, at the Eye Infirmary. A portion had been removed for miscroscopic study, and had been found to be round-celled sarcoma. Roentgen-ray treatment had been well and faithfully tried, with no arrest of or change in the growth. Dr. Callan had asked whether it would be worth while to try the effects of radium before an operation should be undertaken, and had temporarily placed the patient under Dr. Abbe's care. Three of the same radium tubes were placed upon the growth, the eye being protected by a thin lead plate, enveloped in gutta-percha tissue. Plaster-of-Paris casts were taken before and during the course of treatment, to insure accurate demonstration. Four rayings were made of one hour each during one week. A rapid change in the growth was then noficed, and no further treatment was given. Retrograde changes went on so fast that the difference could be noticed from day to day. In four weeks the growth had wholly disappeared, excepting a trifle of grayish thickening on the mucous membrane, and two small, bluish-black spots at the mucocutaneous junction, which, however, were in apparently normal skin. Strangest of all, the sharp edge of the lid contour was perfectly restored as the great tuberous mass subsided, in which all semblance of a lid had been lost. During the five months after the disappearance of the growth, the eyelid retained its appearance of perfect health. The patient then noticed a small, flat, polyp-like growth inside the lower lid, which popped up in front of his pupil one day, and which was subsequently snipped off by Dr. Abbe. It had a small pedicle on an apparently healthy base at the site of the Meibomian glands. Microscopic examination of this showed it also to be a sarcoma, rich in cells, with slight stroma, some of the cells showing mitoses. Nevertheless, to all appearances, the eyelid, inside and out, had the appearance of health.

The sixth patient was the lad with a rapidly growing giant-cell sarcoma of the lower jaw, whose case had been previously reported (Medical Record, August 27, 1904, and who had been presented to the Society at the very beginning of treatment. It was cured by fifteen severe treatments of radium, and remained cured after nearly two years. The teeth were solid and the jaw strong. This case was specially interesting because attention was called by one of the members at the time to the involvement of submaxillary lymphatics near the tumor. These disappeared as the tumor retrograded and ossified, and had never since been found.

The seventh patient illustrated the infallible effect that radium produced on warts of the ordinary type in causing them to disappear. One application was usually sufficient, and they dried up and fell off in about a week. Casts were shown where the wart was a distinct blemish, as on a young lady's lip, and a large one on the outer side of the little finger of a young lady who had for two years submitted to electrolysis and Roentgen-ray treatment in Paris and by American physicians without cure. This was caused to disappear promptly and permanently (six months had now elapsed) by two applications of an hour each. The patient presented, however, showed a much more obstinate and larger wart of two years' growth, covering the entire middle knuckle of the middle finger. It had entirely come away under the use of radium, but two small recurrent spots had required a little more treatment after three months.

The eighth patient showed a rare form of glandular disease of the upper lip. For seven years this man, now 25 years of age, had been greatly annoyed by a persistent tumefied and peeling and fissured condition of the upper lip. Under the mucous membrane could be seen small, yellowish miliary bodies (100 or more), distributed singly and in groups along the middle of the red surface of the upper lip, from one side to the other. These seemed to represent muciparous follicles, chronically inflamed. Dr. George T. Elliot, who had referred the patient to him, regarded them as aberrant sebaceous follicles. The condition had been assiduously treated by able men here and abroad, including Unna, in Hamburg, and Lassar, in Berlin, with no mitigation during seven years. Inasmuch as it represented a type of hypertrophic glandular inflammation, radium was applied to one-half the lip for the purpose of contrast, and with the hope of supplanting the diseased condition by one of radium excitation, in the belief that a substitutive inflammation of a different quality and grade, such as radium induced, might cure the condition. Two applications of fifteen minutes each of one tube of ten centigrammes of radium (300,000), laid on the tender skin of one-half the lip, had already caused a total disappearance of the miliary bodies, and produced a more normal condition of that half than had existed for a long while. Only a fortnight had elapsed, however, since radium treatment was undertaken, and the case could only be reported as under observation, to be shown again later.

Dr. George L. Peabody, in discussing the cases shown by Dr. Abbe, said the effect produced by the radium seemed more like the work of a fairy godmother than anything else that he had ever seen in therapeutics.

Dr. Joseph D. Bryant said the patients and casts just exhibited were the best demonstration he had ever witnessed of the potency of radium therapy. There seemed to be no question that the rays had exerted a decided effect on these various growths. There were certain features in connection with some of the cases that were worthy of special attention, particularly the case in which the ear was involved. It was a well-known fact that it was difficult to eradicate an epithelioma or other malignant growth of the ear by the knife or any other method without producing a decided deformity. In the case Dr. Abbe had shown, however, the disease was apparently absolutely removed, leaving the cartilage intact and showing the characteristic features of normal cartilage. The destruction of warts with radium suggested the probability that it might exercise an equally strong influence on structures that were dissimilar. In the case of the epithelioma of the left nostril there still remained, apparently, a suspicious area of hardening, indicating, perhaps, that the cure was not complete, and the final outcome in that instance would be interesting. In the case of sarcoma of the lower jaw, which was first shown about two years ago, the cure was apparently complete, and the submaxillary gland that was at that time enlarged, and which was probably due to irritation, had disappeared.

Dr. Abbe, in reply to a question, said he had given the radium treatment a trial in two or three cases of cancer of the cervix uteri. In one case, which was pronounced an epithelioma by Dr. F. C. Wood, the radium tube was inserted into the cervix on two occasions, and left there

for about twelve hours. This set up a severe degree of inflammation of a type peculiar to radium action. The cervix became swollen and firm, as if lymph infiltrated, and there was a free discharge of the cervical mucus and of a thick gray lymph secretion. When the patient was again seen, several months later, there was still little or no thickening of the cervical mucosa, and no indication of malignant disease. A section of tissue was again removed and submitted to Dr. Wood, who reported that it showed normal tissue only. The patient had thus far remained free from a recurrence. In another case, where the disease of the cervix was so extensive that an amputation or other operation seemed useless, he curetted away all diseased tissue until firm, tough uterine structure remained, and on the following day placed three strongest radium specimens in the place, which he left for twenty-four hours. The case had been followed for six months by the attending physician. In a case of rectal carcinoma in a very stout woman, a laparotomy was done, revealing a scirrhus of the gut, about eight inches above the margin of the anus. As a resection was deemed inadvisable, the wound was closed. The stricture was then slightly dilated from below, and the tube of radium inserted into the center of the tumor on two occasions, being left there over night. Rapid improvement followed, and with the exception of a small remaining stricture, the woman was in excellent health and had good movements. Good-sized bougies were easily introduced. Of course, the ultimate outcome of the case was doubtful. Dr. Abbe said the only explanation he could give for these effects of the radium was that in some way it restored the vital energy of the diseased or degenerated cell, and produced a retrograde process in the abnormal tissue. In reply to a question as to what percentage of recurrences he expected in the cases where he had applied the treatment, the speaker said that would probably depend upon whether enough had been done; whether the treatment had been carried out sufficiently long. In several cases, the tendency to recurrence was promptly checked by further application of the radium.

Some Clinical Features of Spasmodic Asthma.—Dr. A. Alexander Smith, who presented this paper, said that he would consider only what was ordinarily recognized as spasmodic asthma, and would refer only incidentally to the asthmatic attacks that might be associated with cardiac or renal disease. One hardly knew whether to call asthma a symptom or a disease, and at the very outset we were met with the fact that as yet pathologists had failed to give any satisfactory explanation of the underlying pathological changes in spasmodic asthma, while autopsies revealed only the results of the long-continued action of asthma. We accepted the view, which could only be a theory, that it was due to some as yet undiscovered disturbance in the nervous system, either central or peripheral, which still defied satisfactory explanation. Was the manifestation due to a contraction of the circular muscular fibers of the bronchial tubes? Was it a spasm of the diaphragm? Was it a vasomotor paresis? Was it a bronchiolitis exudativa, as claimed by Leyden? Had the Charcot-Leyden crystals, so often found in spasmodic asthma, to do with the etiology, or were they simply crystals which were produced in the course of an attack? Were the Curchmann's spirals cause or effect? Were the asthmatic manifestations a reflex? Were the pulmonary symptoms merely a local manifestation of irritation of some other part of the body? Was the starting point of such irritation nasal, gastric, intestinal, uterine, ovarian, or in the skin?

The contradictory nature of spasmodic asthma was shown under no circumstances better than the influence displayed by a change of locality. The fact was familiar to all that the change from one house to another, from one floor to another, from one street to another, from one side of the street to the other would often change an attack of asthma. He recalled the remark of the late Dr. Alonzo Clark that "A man may have asthma in New York, and be free from it in Hoboken." He mentioned the case of a young physician in this city who was free from asthma while in New York, but invariably had an attack when he went to the Adirondacks. He had another patient who suffered from attacks of asthma in New York; when they became intolerable he went to Pittsburg, and within forty-eight hours, in the midst of the smoke and soot and dirt of Pittsburg, his asthma entirely ceased. The direction of the wind, in connection with asthma, also illustrated the contradictory nature of the condition. The majority of asthmatics were rather more comfortable when the wind blew from the eastern quarter; but let it veer to the west, particularly to the northwest, with clear and dry weather, and asthmatics were apt to have their symptoms decidedly aggravated. While it was claimed by many observers that hay asthma and spasmodic asthma were two separate and distinct affections, he had seen so many cases of spasmodic asthma in which there was a history of the first attacks manifesting themselves as hay asthma, that he was inclined to think that there was a more decided relationship between hay asthma and spasmodic asthma than was ordinarily recognized. There was perhaps in all these cases the same underlying condition of the nervous system, which predisposed the patient, under different existing conditions, to attacks of one or the other.

The contradictory nature of spasmodic asthma was further shown by the results of treatment during the paroxysm, or in the interval between them. Measures that claimed to relieve were numerous, but it had frequently been the speaker's experience that measures which relieved some cases failed in others; and even in the same case measures which relieved at one time failed at another. A full opiate, given preferably as morphine by hypodermic injection in conjunction with atropine, would frequently cut short a paroxysm. It had many objections, however, and the necessity of repeating it and the consequent danger of the contraction of the habit made it undesirable in the majority of cases. The inhalation of small quantities of chloroform or ether sometimes gave relief, but the effects were very evanescent. Belladonna, another much vaunted remedy, in his experience brought relief only when it was pushed to the point of producing very unpleasant symptoms. He had occasionally seen a paroxysm cut short by the administration of full doses of quinine—twenty grains or more. Stramonium, best used in the form of cigarettes and the smoke inhaled, sometimes gave satisfactory relief. His experience with the so-called nauseant remedies had usually been such as to produce marked disturbance of the digestive system, with questionable beneficial results. The inhalation of a few drops of nitrite of amyl would sometimes afford relief. The most useful of the diffusible agents was nitroglycerin, administered in doses of 1-100 grain, and repeated at varying intervals of from one-half to two hours. He had faithfully tried the so-called breathing exercises, but confessed his great disappointment in the result. The use of a spray of three or four per cent. cocaine solution in the nostrils would often give relief, but its effects were very evanescent, and with this remedy, as with the morphine, the danger of acquiring the habit should not be lost sight of. The inhalation of oxgen gas, or rather a combination of nitrogen and oxygen, as it was found in the market to-day, would produce a certain amount of relief in some cases. During the past two years he had used adrenal extract in spasmodic asthma, and fairly satisfactory results were obtained in some cases by its application as a nasal spray in the strength of a 1-1,000 solution. Used internally, it had not produced satisfactory results, and his experience with its hypodermic use was limited. Ofttimes, agents which produced sleep modified the paroxysms, and brought great comfort to the patient. The best agents he had found for that purpose were paraldehyde and chloralamide, which seemed quite

free from depressing after-effects, especially the former, which he usually gave in doses of from a half to one teaspoonful, well diluted in water, and repeated in two or three hours, if necessary. The chloralamide he gave in fifteen grain doses, repeated in two or three hours, if necessary.

In the prevention of attacks of spasmodic asthma, the speaker said it was hardly necessary to emphasize the importance of controlling or eliminating, as far as possible, any known exciting cause. One could not attach too much importance to the necessity for such care, whether the existing causes were from agents from without, or from disturbances from within the patient himself.

In speaking of remedies of a more or less specific character in the treatment of spasmodic asthma, Dr. Smith gave the iodides the first place. Disagreeable as they often were, both as to taste and effects, he still insisted on their use. The experience was common in many cases that if the iodides were taken pretty constantly there was no recurrence of the attacks for long periods. He rarely gave more than fifteen grains daily, and then usually in combination with a bromide. In the order of their beneficial effects, he placed the potassium salt first, then the sodium, and then the strontium, while their order of tolerance was exactly the reverse. Another remedy upon which he placed much reliance was cod liver oil, given continuously during the cold weather. In many cases the results of this treatment were most satisfactory. Arsenic was another agent of value in many cases, preferably given in small doses for a long period.

Dr. Andrew H. Smith raised the qestion as to whether the pathological condition was the same in all these cases; whether in some instances we were dealing, perhaps, with a spasmodic contraction of the air tubes, and in other cases of the blood vessels. Spasmodic asthma occurring in the course of renal trouble suggested the presence of some toxic substance in the blood that affected the vasomotor system, and the difficulty of breathing in those cases was probably dependent on a pulmonary ischemia rather than upon a lack of air in the air-cells. The speaker said that in some experiments he made years ago with oxygen inhalations, he was able to demonstrate that some cases were immediately relieved by such inhalations, while in others they had no effect. In the latter class, it seemed to the speaker that the trouble was in the blood-vessels more than in the air-tubes.

Dr. George L. Peabody said that Dr. Smith's paper had illustrated the extreme capriciousness of spasmodic asthma, in both the causative relations and the treatment. The speaker recalled the case of a medical student in whom violent attacks of asthma, lasting several days, were provoked by stroking a cat. In regard to the treatment of the persistent and less severe forms of this affection, Dr. Peabody said he depended rather more on the nauseant remedies than did the reader of the paper, and the results he had obtained from the use of tartar emetic had been fairly good. A grain of the drug was dissolved in a tumblerful of water, and the patient was given a teaspoonful of the solution, about 1-64 of a grain, repeated every hour or half hour. Given in this way, it never nauseated, and frequently relieved the attack. In some cases he had seen relief follow the inhalation of a spray of the wine of ipecac. With this method, the patient should be instructed to rinse his mouth very carefully after each spraying, as swallowing the solution would be apt to nauseate him. Dr. Peabody said he agreed with Dr. Smith that paraldehyde was especially valuable in some cases. When the stomach was very irritable, it could be given per rectum in peptonized milk or in water, in doses of from one to two drams.

Dr. Charles L. Dana said he had observed a number of cases where the attacks of spasmodic asthma had disappeared comparatively early in life, and the patients had become victims of a severe type of migraine, and, in one instance, of epilepsy. Such cases might lead to the inference that spasmodic asthma was a periodical discharging neurosis, similar perhaps, to migraine, and distinctly, to epilepsy. Both of the two latter affections were benefited by the bromides, the antiperiodics, and drugs of the alkaline class. The speaker said that his observations had led him to regard spasmodic asthma as a periodical neurosis, due to an unstable nerve center, like migraine, the attacks being excited like other discharging neuroses by peripheral or central irritations.

Dr. Beverley Robinson said that while he had seen many cases of spasmodic asthma relieved by the removal of nasal polypi, cauterization of the nose, etc., he had rarely seen a permanent cure follow such treatment. Of the manifold remedies that had been advocated in the treatment of this affection, he regarded the syrup of hydriotic acid as the best, *per se*. He also favored potassium iodide, where the patient could tolerate it, and frequently, as a useful adjunct, Hoffman's anodyne. The speaker recalled the case of a child that would suffer from attacks of spasmodic asthma and urticaria from taking milk, but these attacks would not occur when bread was taken with the milk. In that case the attacks were eventually outgrown.

Chicago Medical Society.

At a meeting, held December 6, 1905, Dr. William J. Mayo, Rochester, Minnesota, read a paper, by invitation, entitled "Radical Removal of Cancer of the Stomach." Numerous examples were cited to show the inconsistency of looking for a medical side to this question. There were two reasons why the medical profession had been slow to apply surgical methods to the cure of this common malady. These were: (1) The frightful mortality of early operations, which discouraged patient, physician, and surgeon. (2) The difficulties and uncertainties of establishing an early diagnosis. The death-rate from early operations was appalling. The average mortality at the time of Billroth's death was over 60 per cent. The mortality at present in the hands of men of experience in operable cases was not above 10 per cent., and in suitable cases it was nearer five per cent. An exploratory incision was the only way an early diagnosis of cancer of the stomach could be established. The most careful, painstaking methods of examination, including laboratory methods, should be insisted on, but should not be unduly prolonged. The clinical history, with chemical examination of the stomach contents, etc., might lead to the suspicion of carcinoma of the stomach, and it was upon these physicians should act if they would be truly conservative. Dr. A. J. Ochsner said that Dr. Mayo had done much to clear up the living pathology of carcinoma of the stomach, on account of having operated on such a large number of cases. The high mortality following operations for carcinoma of the stomach in the early days was due to conditions which no longer existed to a very great extent, since the methods of operating had been greatly improved by Mayo, Mikulicz, Krönlein, Czerny, and Robson. Formerly a large part of the mortality came from secondary complications, such as pneumonia. This was undoubtedly due to unnecessary traumatism and consequent infection by way of the esophagus. This complication had been disposed of by the simplification of the operation. The surgical treatment of ulcer of the stomach had cleared up cases which otherwise would have become cancerous, and had placed the surgeon in a position in which he could reasonably approach these cases at a time when their successful treatment was a comparatively simple matter. Shock was one of the causes of high mortality, but this had been reduced materially by simplifying the operation. Infection had been practically eliminated. Dr. Arthur Dean Bevan said that surgeons were almost unanimous in accepting the views presented by the essayist. It had been demonstrated that carcinoma of the stomach was a surgical disease, and that the modern work of the last five years had been sufficiently encouraging to urge surgeons to operate more frequently

than they had done before. Dr. E. Wyllys Andrews said the justification for the radical in preference to the palliative operation in cases of carcinoma of the stomach was based upon the results obtained and the relatively low mortality from the more modern method. He did not believe, however, that the time would ever come when palliative operations would be abandoned, because he had seen the lives of patients prolonged four and six months, yes, even one and two years, by such operations. Dr. Alexander Hugh Ferguson supported Dr. Mayo in the position he had taken. He had been fortunate enough to operate on one patient, doing a pylorectomy, who had been apparently cured. It was an early case, because there was early pyloric obstruction. He thought it would be a fortunate thing for the sufferers from carcinoma of the stomach if obstruction at the pylorus were the first symptom of their disease; then he ventured to say 95 per cent. of them would be saved from an untimely death. Dr. Fenton B. Turck spoke of the importance of differentiating more clearly between carcinoma of the stomach and what was not carcinoma. Dr. Frank Billings said carcinoma of the stomach was a surgical disease. The motility of the stomach was one important factor in separating the medical from the surgical cases. When the motility of the organ was disturbed and stagnation occurred, it was either a medical or surgical case, and the diagnosis would clear up which it was. If it turned out to be a case of pyloric stenosis, it was surgical; if it proved to be a case of diminished motility of the stomach, with a large pyloric orifice, it was usually medical. He recalled patients whose lives had been prolonged for more than a year following gastroenterostomy. Dr. Carl Beck had had an opportunity to observe a patient upon whom he did a radical operation for the removal of carcinoma of the stomach five years ago. He had had to do a secondary operation for carcinoma elsewhere, on the same patient, and during this second operation he examined carefully the stomach region and found it normal. Dr. Mayo, in closing, felt confident that the near future would reveal methods of making diagnoses in these cases more readily than now, and that as a consequence a considerable percentage of cases of carcinoma of the stomach would be operated upon much earlier. The surgeon could not always make a pathological diagnosis in these cases, and he thought anyone who said that a surgeon should not operate without a pathological diagnosis was in error. He had eliminated fifteen cases from his statistics because pathologically as shown by the microscope, they were not carcinoma but ulcer of the stomach.

Philadelphia Neurological Society.

At a stated meeting held November 28, Dr. Philip Sheaff demonstrated "A Case of Locomotor Ataxia Presenting Unusual Arthropathies of the Feet." The patient was a man, 38 years old, who gave a history of syphilitic infection, with marked enlargement and deformity of the feet. The Achilles tendon jerks were absent and the knee jerks could be elicited only on motor reinforcement. The pupillary reactions were preserved and there was only slight pallor of the optic discs. Occasionally there was girdle feeling and there was some difficulty in the expulsion of urine. Dr. J. H. W. Rhein presented "A Case of Injury to the Face Followed by Paralysis of Several Cranial Nerves." The patient was a woman, 55 years old, who had been struck on the left side of the face by a hawser while watching the departure of a vessel with friends on board. There was ptosis of the upper eyelid on the injured side, with dropping of the corner of the mouth, partial obliteration of the nasolabial fold, inability to rotate the eye outward beyond the median line, and left temporal hemianopsia with the Wernicke pupillary reaction on the temporal portion of the left retina. At the time of the accident there had been free epistatis, and it was found that the nasal bones had been broken. The lesion was supposed to be a fracture of the wings of the sphenoid bone with injury to the optic, the third, the fourth, part of the fifth, and the sixth nerves. Dr. Charles K. Mills exhibited "A Case of General Myokymia." The patient was a man, about 50 years old, who presented twitching of fasciculi and bundles of muscles in various parts of the body without known cause and of uncertain origin. Dr. Thomas Luther Coley presented a communication entitled "A Rapidly Fatal Case with Symptoms Suggesting Myasthenia Gravis." The patient was a man, 28 years old, who was seized with difficulty in swallowing, nystagmus, enfeebled ocular movements in certain directions, and elevation of temperature, with a fatal termination in the course of seventeen days. After death the thymus gland was found persistent and enlarged, and the ganglion cells of the anterior horns of the spinal cord were the seat of chromatolysis and nuclear displacement. There was no lymphoid infiltration of the muscles. The case also bore some resemblance to Landry's paralysis. Dr. D. J. McCarthy reported "A Case of Unilateral Tuberculous Meningitis," and he demonstrated the specimen. The patient had been a man suffering from pulmonary tuberculosis in whom hemiplegia set in with focal epilepsy. After death a meningo-encephalitis was found in the distribution of the middle Sylvian artery on the side of the brain opposite to that of the symptoms during life. Drs. G. A. Moleen and Wm. G. Spiller presented a communication entitled "Chronic Anterior Poliomyelitis in the Adult, with the Report of a Case with Necropsy." The patient had presented symptoms of spinal progressive muscular atrophy, while after death pronounced degeneration of ganglion cells in the anterior horns of the spinal cord were found, together with slight degeneration of the crossed pyramidal tracts. No similar report could be found in British or American literature, although some reports can be found in the German and French literature.

Pathological Society of Philadelphia.

At a stated meeting held November 9 Dr. B. Franklin Royer presented, by invitation, a series of brains and spinal cords illustrating the morbid anatomy of cerebrospinal fever. Dr. D. J. McCarthy exhibited specimens illustrating tuberculous meningitis. Drs. B. Franklin Stahl and John Funke exhibited the brain and spinal cord from a case of pneumococcal meningitis. Dr. Ralph Lavenson exhibited a specimen of hemorrhagic meningitis from a case of alcoholism with nephritis. Dr. John Funke exhibited specimens of hypernephroma with metastasis to pleura and lungs. Dr. Wm. Pickett presented a communication entitled "Syringomyelia with Report of Two Cases." He described the lesions found in two cases of gliomatosis with cavity formation in the cord, and he demonstrated sections of the diseased tissue. Drs. Wm. G. Spiller and E. Rawlings exhibited a specimen of meningomyelitis with intense swelling of the spinal cord and of the roots of the cauda equina. The patient was a child five years old. Lumbar puncture was practised and only mononuclear leucocytes were found in the fluid. After death the spinal membranes were greatly thickened and the cord unusually large, while distinct swellings were visible on the roots of the cauda equina. The conditions were suggestive of a tuberculous origin, but no tubercle bacilli or other microorganisms could be demonstrated. Dr. G. Canby Robinson presented a communication entitled "Bacteriological Findings in Fifteen Cases of Epidemic Cerebrospinal Meningitis, with Special Reference to the Isolation of the Meningococcus from the Conjunctiva and the Circulating Blood." The microorganism was found in the circulating blood in one among four cases examined from this point of view. Dr. Allen J. Smith presented a communication entitled "The Processes Involved in and the Significance of the Invasive Stage of Febrile Affections."

At a stated meeting held November 23 Dr. Warfield T. Longcope exhibited a specimen of "Echinococcus of the Lung," discovered accidentally after death in the body of a

patient dead from typhoid fever. Dr. Joseph McFarland exhibited a specimen of "Echinococcus of the Spleen." Some doubt existed as to the nature of the specimen, but by a process of exclusion it was decided that it could be nothing else than the remains of an echinococcus cyst. The specimen was obtained from a cadaver in the dissecting room and consisted of a globular mass embedded in the substance of the spleen. It was made up of a hard fibrous or cartilaginoid capsule with liquid contents containing cholesterin. Dr. Allen J. Smith exhibited a specimen of "Daughter Echinococcus Cysts." The specimen came from the collection of the University of Pennsylvania and had been prepared by the late Professor Joseph Leidy, who had obtained it from one of the lower animals. Drs. Addinell Hewson and A. G. Ellis exhibited specimens of "Echinococcus Cysts of the Liver and Kidney." The cyst of the liver was in every way characteristic and in its fluid contents hooklets of the parasite were discovered. The formation in the kidney, which was from the same subject, was of solid consistency with a distinct colloid or gelatinoid capsule, but hooklets could not be demonstrated. The specimen was obtained in the dissecting room and there was evidence that the cyst of the liver had undergone suppuration and had been in part discharged through an adventitious opening in the abdominal wall. Dr. Courtland Y. White exhibited specimens of "Echinococcus in Animals" and he demonstrated slides of scolices. Dr. W. M. L. Coplin exhibited specimens of hooklets and scolices obtained at operation on a case of echinococcus cyst of the liver. Dr. John Funke exhibited a specimen of rupture of an aneurysm of the aorta into the pericardium and also a specimen of laceration of the septum between two aortic semilunar cusps. Dr. Funke also read a paper entitled "Chemical and Microscopical Study of the Urine During Life Followed by Histological Examination of the Kidneys from the Same Patients." As the result of a large number of examinations it was found that albuminuria, even when present, was not constant, and that there was no invariable relation between the presence of albumin and tube casts in the urine and the actual state of the kidneys. Dr. Joseph Walsh read a paper entitled "Lesions of the Kidney in Pulmonary Tuberculosis." He reported the results of a study of the urine and of the changes in the kidneys in some sixty cases of pulmonary tuberculosis. Albumin, tube casts and tubercle bacilli were found in the urine with varying frequency; and tubercles of characteristic structure and tubercle bacilli, independently and associated, and also fibroid changes of varying degree and distribution were found in the kidneys after death. Drs. Lawrence F. Flick, M. P. Ravenel, and J. W. Irwin presented a communication entitled "Pneumococcic Infection in Relation to Hemorrhage in Pulmonary Tuberculosis." They dwelt upon the frequency with which infection with pneumococci complicated the course of pulmonary tuberculosis, and they proposed the term pneumococcosis as descriptive of the condition. The association is characterized especially by the appearance of blood in the expectoration, high and irregular temperature, and symptoms of profound intoxication not usual in cases of uncomplicated tuberculosis. The recognition of the condition is made by examination of the sputum and animal inoculation.

Specific Treatment of Tuberculosis. — E. Maragliano finds that all of the products obtained from the blood, milk, and tissues of animals immunized against tuberculosis have a curative action against the disease. The blood serum of these animals has a true therapeutic action in man especially in the early stages of the disease. Antituberculous substances introduced by way of the digestive tract pass into the blood and exercise an evident therapeutic action. Tuberculous toxins introduced by the digestive passages may develop in man and in animals antituberculous substances, and exercise a therapeutic action.—*La Riforma Medica.*

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Diseases of the Ear, Nose, and Pharynx. By St. John Roosa, M.D., and Beaman Douglas, M.D. 8vo, 621 pages, illustrated, muslin. The Macmillan Company, New York. Cloth, $3.00.

A System of Medicine. Edited by Thomas Clifford Allbutt, M.D., and Humphry Davy Rolleston, M.D. New edition revised with additions, 8vo, 1,209 pages, illustrated, muslin. Vol. I. The Macmillan Company, New York. Cloth, $5.00.

OBSERVATIONS ON NEPHROPTOSIS AND NEPHROPEXY.*

By ARNOLD STURMDORF, M.D.,

NEW YORK.

GYNECOLOGIST TO THE SYDENHAM HOSPITAL, SURGEON TO THE METROPOLITAN HOSPITAL.

The scope of the general subject of intraabdominal ptosis makes it essential to emphasize that the present communication is necessarily limited to a curtailed practical consideration of that phase of the condition most amenable to correction, namely, nephroptosis.

The recorded observations on ectopic kidney date from the year 1561 and constitute a voluminous though widely-scattered literature, which is characterized by a lack of comprehensive unity on every phase of the subject from nosology to therapy.

Thus, while it is generally conceded that in a certain proportion of the cases, this condition embodies an actual though ill-defined clinical and pathological entity, it will nevertheless be found classified and discussed, even in some of the most recent treatises on the subject, as a topographical anomaly, or, in other words, as a simple anatomical curiosity.

Such incongruity and indefinitude pervading this whole subject, it devolves upon those whose special interest brings them into most frequent and responsible association with these cases, to submit for comparison and criticism such observations and impressions as result from their wider study and larger experience.

To the present writing, all statistics bearing upon the frequency of nephroptosis are based upon the existence of palpable kidneys, of whatsoever degree or significance. It should be borne in mind, however, that a kidney that is accessible to palpation has not necessarily trespassed beyond its physiological limits, for it is now established beyond controversy that the kidneys normally display a varying degree of mobility. It is difficult to establish a differentiating border line between such physiological mobility and pathological prolapse, inasmuch as the range of mobility seems to present no proportionate index in the intensity of its clinical manifestations.

It will be observed that in some instances a degree of mobility exceeding any conceivable normal range proves entirely unproductive of discomfort, while in other instances a kidney presenting a mobility that, according to some authorities could be justly interpreted as entirely within normal limits, demands radical correction for the relief of local and general symptoms.

In view of such clinical disparity, the question naturally arises, what constitutes nephroptosis? Abnormal visceral mobility represents abnormal visceral support, the recognition and correction of which should be based upon a clear conception of the mechanism of normal support and the elements involved in the disturbance of such normal support.

The nature of normal kidney support has been the subject of speculation and controversy from the time of Bartolini to the present day. Every structure, anatomically or functionally related to these organs, has been successively depicted at one time or another as representing their supporting element, until Wolkow and Delitzin demonstrated the functional passivity of *all* textural support and the dominating influence of intraabdominal pressure in maintaining the topographical stability of the kidneys.

The significance of these findings, which were obtained by observations on the vertically suspended cadaver, prompted the corroboration of their validity in the living, as follows:

Modern surgery of the more deeply situated upper abdominal viscera, resorts to postural aids, utilizing gravity and atmospheric ingress to favor accessibility and isolation of the surgical objective point; the patient is placed in what is termed the reversed Trendelenburg position, that is, with the upper parts of the trunk elevated. In this position, which to a degree reproduces in the living, the postural element in Wolkow and Delitzin's investigations on the dead, the opened peritoneal cavity will uniformly reveal kidney mobility, with varying degrees of ptosis that were not manifest in any manner through the intact peritoneal sac.

Such experimental induction of artificial kidney ectopia establishes the stabilizing function of intraabdominal pressure and the purely auxiliary nature of ligamentous suspension in kidney support.

The potency of intraabdominal pressure as a supporting element, however, is entirely dependent upon one contributory factor of the deepest significance in the solution of our problem; namely, the conformation of those depressed areas in the posterior abdominal wall normally occupied by the kidneys. The more extensive the contact area between the posterior kidney surface and these depressions, the more efficacious the retentive power of intraabdominal pressure.

Omitting theoretical considerations, normal kidney support may be practically defined as the resultant of two essential factors, a retaining pressure of adequate intensity and a receptacle of accurate conformation. The retaining pressure is exerted by the normal tension of the general peritoneal sac applied to the anterior kidney surface in the manner of an inflated cushion, propping the organ against its receptacle. This pressure is reflexly regulated by the activity of the abdominal muscles.

The receptacles applied to the posterior kidney surface are formed by the declivity existing

* Read before the Harlem Medical Association, December 6, 1905.

on each side of the anterior aspect of the lower dorsal and upper lumbar spine. They are funnel-shaped recesses, narrow below in the male, more cylindrical and shallow in women, a peculiarity more marked on the right side and appearing with the broadening of their pelvis at the advent of puberty. Deviations in the conformation of these receptacles from the lines of the posterior kidney surface, constitute the main predisposing factor in the production of nephroptosis.

The causes of such deviations are embaced in the whole category of congenital and acquired skeletal abnormalities, and while the external manifestations of skeletal deficiencies have received brilliant illumination from modern orthopedic science, their clinically related internal manifestations, or visceral orthopedics, constitute an unwritten chapter.

In the presence of skeletal inadequacy of the receptacle, any given factor, sufficient to alter, even temporarily, the intensity or direction of intraabdominal pressure, will produce nephroptosis, and a kidney so dislocated can never spontaneously regain or retain its normal position in the erect posture.

The pressure that maintains normal kidney stability, in the presence of an adequate receptacle, will perpetuate its instability in the absence of such proper resting place.

This perpetuation of such ectopia or, in other words, the inability of the kidney to retain its normal topographical relations under the given conditions, cannot logically be attributed to mere insufficiency of the receptacle only, for at best the relation between the kidney and its receptacle is one of limited surface contact.

Dislocated kidneys will invariably be found associated with characteristic skeletal stigmata. Becher and Lennhof noted the ratio between length and circumference of the trunk presented by this skeletal type, and found that a certain index invariably bespoke the existence of nephroptosis.

Not only mensural characteristics, but the structural, nutritional, and functional derangements of bones, ligaments, and muscles that result from infantile disease affecting these structures, such as syphilis, rickets, poliomyelitis, and so on, are presented by this class of patients.

Thus the possessor of a prolapsed kidney probably had club foot or has acquired flat foot, shows a tendency to or existing herniæ, spinal curvatures, proneness to articular dislocations and fractures, uterine and ovarian displacements, and prolapse without apparent intrinsic cause.

Nephroptosis has been found in infants. W. R. Stewart reports a case, in which an exploratory laparotomy for intestinal obstruction revealed a prolapsed kidney. Abt and Morris have collected and reported a number of similar instances. In the abdominal protrusion of rickets, familiarly known as "pot belly," nephroptosis can usually be demonstrated.

It is a recognized law in physics, that a body impinged against a given surface is subject to deflection, according to the angle of the plane of that surface. This law governs in establishing and maintaining visceral equilibrium within the abdominal cavity, against the displacing force of gravity and the functional activity of the mobile abdominal contents; but for the influence of such planes in deflecting and directing abdominal pressure, every erect biped would carry his abdominal contents in his pelvis. The mechanism of pressure deflection in maintaining pelvic visceral equilibrium was elucidated by the writer in a recent publication;* the principles there elaborated apply to all the other abdominal viscera.

Admitting the existence and the dominating influence of such planes, in directing or misdirecting pressure, it follows that skeletal deviations, by permanently altering the angles of the deflecting planes presented by the inner surface of the abdominal cavity, must result in a permanent deflection of the organs impinged against such planes by the force of intraabdominal pressure.

The earlier in life the kidney is deflected from its normal plane, the less disturbance its malposition will induce. Such early development of nephroptosis will result in one of two conditions: either there will be a spontaneous fixation of the prolapsed organ, usually at the pelvic brim, or there will be established what may be interpreted as a compensatory equilibrium among the abdominal contents, thus creating a tolerance of the abnormality.

Ectopic kidneys of early development, will present the widest possible range of mobility, with the minimum of disturbance, while the more recently developed ectopia, with limited mobility will announce its existence in unmistakable symptoms of local and general significance.

The symptomatology of nephroptosis represents the most prolific chapter in its literature, and it will serve the practical purpose of the present communication, to skirt only the general elements involved in its clinical manifestations, rather than enter into a detailed enumeration of individual symptoms.

The clinical significance of nephroptosis is proportionate to the disturbance manifested within the prolapsed kidney and by the prolapsed kidney upon associated viscera.

A prolapsed organ is more exposed and more susceptible to injurious influences than one normally situated; the more obtrusive results of kidney dislocation, such as strangulation from torsion and impaction find full recognition, while the more insidiously developing pathological accompaniments, although of equally serious import, are almost unknown.

Segregation and modern chemicophysical urinalysis will reveal unsuspected functional and organic abnormalities in many cases. Ureteral catheterization will frequently encounter angulations productive of a hydronephrosis that eluded ordinary bimanual palpatory exploration.

When it is recalled that the ultimate tendency of augmented intrarenal pressure from impeded urine drainage is degeneration and absorption of the renal parenchyma, the importance of recognizing and relieving the early manifestations of such impediment becomes apparent. It is generally claimed that such pathological results from movable kidney are of rare occurrence; this claim must be taken as unsubstantiated, so long as pathologists omit to seek and note the existence and etiological relations of abnormal mobility in their investigations of kidney degenerations.

The familiar manifestations of nephroptosis resulting from the distortion of the normal topographical and physiological relations of the kidney represent the accessible knowledge on the subject; they are the gastrointestinal, biliary, and nervous phenomena that make up the conventional chapter on symptomatology, and are

*Perineum, Perineorrhaphy, and Prolapse, MEDICAL RECORD. April, 1905.

simply alluded to in passing to the bearing of nephroptosis on gynecological conditions.

The genitourinary system represents an embryological and clinical unity, and it is but natural to find that disturbances in its components are manifested by associated, interdependent, and undifferentiable symptoms. Unfortunately, ethical refinement in modern specialistic distinction places an arbitrary deadline between the renal and gynecological zone, to the detriment of the patient and impediment of our knowledge.

The inexplicable persistence of so-called ovaralgia, ovarian dysmenorrhea, intermenstrual dysmenorrhea, and other obscure manifestations, that have cost many women their ovaries if not their lives, will usually find ready explanation in the existence of a prolapsed kidney.

The investigations of Edebohls have established a causal relationship of nephroptosis to appendicitis, yet many an unoffending appendix is sacrificed, owing to a sensitive McBurney's point, the result of iliohypogastric or ilioinguinal neuralgia, accompanying a dislocated kidney. An illustrative case under the writer's observation, presented a marked painful varicocele of the right broad ligament, the result of nephroptosis and productive of a disabling right-sided dysmenorrhea. A prominent surgeon removed the appendix; a recognized gynecologist suggested cervical divulsion and curettage, which was faithfully carried out, yet the incapacitating dysmenorrhea persisted until permanently relieved by nephropexy.

Unbiassed observation of many cases of nephroptosis will bring the conviction that no inconsiderable number manifest subjective and objective symptoms of a gravity that calls for serious therapeutic effort.

Normal restitution in nephroptosis would imply normal restitution of the skeletal deviations productive of the ptosis. Such skeletal deviations represent the results of accidents and diseases incidental to skeletal growth and development, and it follows that the time for the prevention and correction of such deviations falls into the developmental period of the osseous framework.

The restoration of normal internal as well as normal external conformations should be our orthopedic aim; the organic and functional spinal deviations of early life, the infantile paralyses, the muscular and ligamentous insufficiencies, should receive consideration from the point of normal internal as well as external topography. Much is being accomplished in the correction of external skeletal abnormalities; much may be accomplished by attention to the visceral displacements induced by such abnormalities.

Kidney dislocation once developed, nothing short of surgical fixation will reestablish its normal stability. Palliative treatment undoubtedly yields results, but of temporary duration. It is only natural that the dorsal decubitus should relieve symptoms due to a prolapsed kidney; it cannot, however, result in fixation of such a kidney, no matter how long maintained.

Nor is kidney support a question of fat supply. The fatty capsule surrounds the kidney in a protective capacity and not as a support. We find loose kidneys in very fat people and fixed kidneys in the very lean. Those afflicted with acute wasting diseases do not develop nephroptosis, while, on the other hand, every surgeon who practises nephropexy has frequently been compelled to remove very large masses of perirenal fat, in the preparatory denudation of kidney fixation. Notwithstanding all this, palliative measures must frequently be employed, as adjuvants to nephropexy, or for the control of concomitant conditions.

Thus, the abdominal belt will add comfort in the diastases and relaxations of the abdominal muscles, found in some of these cases, but it cannot in any manner support a prolapsed kidney. The abdominal muscles are the guardians and regulators of intraabdominal pressure; they are constantly active, automatically yielding when the pressure increases and contracting when it diminishes. Loss of tone and function in these muscles cannot be replaced by elastic webbing.

It is impossible to hold a prolapsed kidney in normal position by any endurable pressure or tension exerted through the abdominal wall; not even the trained hand of the examiner can restrain a movable kidney; coughing, sneezing, and muscular exertion, all of which augment intraabdominal pressure, will displace hand or pad, and permit the kidney to fall into its abnormal position, where it will be as firmly held by the compressing or constricting appliance which thus defeats its own object.

The keynote in the therapeutics of nephroptosis is permanent fixation. At the present time, permanent fixation can be realized with certainty and comparative safety, by the adoption of modern methods of nephropexy.

The mortality of this operation in experienced hands, is about equal to that of exploratory section, and its results must establish it as the legitimate procedure in the cure of nephroptosis.

In the MEDICAL RECORD of June 22, 1901, I published a flap method of kidney fixation, which, with the omission of the transparenchymatous suture, presents the technique adopted in the majority of my cases; it should be mentioned, however, that no single procedure is applicable to all conditions.

During nineteen years of public and private service, 112 cases of nephroptosis came under observation, of which 83 were operated, all in the course of the last six years. In this series, no mortality and three accidents were encountered; an injury to an abnormally attached, accessory renal pelvis, and two instances of urinary fistulæ, resulting from superficial parenchymatous lesions produced in detaching a very adherent friable capsule.

Much should be added that could be said in connection with technique; the accidents and incidents of convalescence; the results, etc., but time limit forbids and this sketchy outline of our subject must stand as a condensed report of a practical and theoretical study of the subject under discussion, which is submitted for criticism and discussion from the conviction that in this manner only can accumulated experience ultimately crystallize into a concrete and systematized elucidation of this clinical problem.

51 WEST SEVENTY-FOURTH STREET.

Hospital Cars in Germany.—The Prussian ministry for railways has placed at every important railway center throughout the kingdom a magnificently built and appointed car for the transport of the sick. These cars have been specially fitted up from plans supplied by sanitary authorities. Spring beds and every medical device for the alleviation of suffering during transit have been utilized. There are gas stoves for cooking, rooms for attendants, and ingenious devices for muffling the sound caused by the motion of the train. These cars are intended especially for use in case of an accident, but they will also be at the service of any invalid needing transportation.

THE RÔLE OF SALINE SOLUTION IN THE TREATMENT OF PNEUMONIA.*

By J. MADISON TAYLOR, A.M., M.D.,

PHILADELPHIA.

The general treatment of pneumonia has been reviewed so thoroughly in the papers that have preceded mine that I will limit my remarks to one of its phases, namely, the means which seem best fitted to insure efficiency of the body's autoprotective processes throughout the entire febrile stage of this fatal disease.

Whatever theory of immunity we adopt, whether we conclude with Buchner that the blood protects the body through the presence in this tissue of "alexins"; whether with Ehrlich we grant the tissue-cells the power to secrete "receptors"; whether we agree with Sajous that the internal secretions supply the needful protective agents to the blood, the fact remains that the life-fluid is unquestionably endowed with a substance capable of staying the hand of death when conditions are such as to enable it to act unhindered. "We know now," recently wrote Behring, "that immunizing antibodies regularly appear in the blood wherever an infectious disease terminates in recovery." Is this not the one feature of the problem which should command our keenest interest? Have we not here the one great weapon through which it is possible to reach the deadly pathogenic elements? It is to this weapon and to the preservation of its integrity as a potent means of attack that I wish to refer.

It is well known that in 1889 F. P. Henry of Philadelphia employed saline hypodermoclysis in the treatment of certain cases of pneumonia. These were, as he specifies,[1] however, cases "of the severest type" and "desperately ill." The value of this procedure in surgery had suggested its use in pneumonia to others both in this country and in Europe, and between 1892 and 1900 especially it was tried in quite a large number of cases. In 1899 C. A. Penrose[2] also advocated hypodermoclysis, but in combination with oxygen inhalations and bleeding. Here again, however, the measure was only used in "desperate cases," practically as a last resort. In England it was tried under the same conditions. Ewart and Percival,[3] for instance, having used it in six cases that were "severe and of uncertain and extremely anxious though not hopeless prognosis" concluded that the injections "were powerless to check the fatal course" in "the worst type of cases." The use of this valuable measure, which even in moribund cases sometimes restores life, has thus been associated with the gravest stage of the disease and recommended for trial "in desperate cases," as Tyson does in the last edition of his text book.

The object I have in mind is not to be attained by the use of saline solution under these discouraging conditions. We do not preserve economically the integrity of the immunizing principles of the blood when we wait until the system is practically overwhelmed with toxins; until the functions of the cells that produce them are well-nigh paralyzed; until the lungs are engorged to such an extent that cyanosis occurs; until pulmonary edema is present or threatened; until the overworked kidneys can withstand no further sudden assaults of toxic wastes; until the blood, already poor in oxygen can hardly bear dilution, and finally until the nerve centers are so dulled that they no longer respond to peripheral impressions. As well wait for the moribund stage to occur in a case of diphtheria before using antitoxin as to employ saline solution during this stage of desperate struggle.

Very different is the conception of the use of saline solution to which I now refer, that due to Sajous of Philadelphia. Here, all the untoward features just reviewed are taken into account, and the aim is eminently in keeping with the most advanced teaching of experimental research, namely, "to preserve and enhance the blood's bactericidal and antitoxic properties from the outset of the disease." This was embodied nearly three years ago by Sajous[4] in a sentence which should be carefully noted, since it has already been instrumental in saving life, viz., "The primary effect of deficiency of alkaline salts in the blood being to inhibit nutrition, to impair the efficiency of, and finally arrest the protective functions of the organism, it constitutes one of the most active causes of death."

It is needless to lay stress on the pathologic importance of the blood's alkaline salts. A brief quotation from Howell's recently published "Physiology" will suffice. The salts of the blood "have most important functions," writes this eminent physiologist; "they maintain a normal composition and osmotic pressure in the liquids and tissues of the body, and by virtue of their osmotic pressure they play an important part in controlling the flow of water, to and from the tissues. Moreover, these salts constitute an essential part of the composition of living matter. In some way they are bound up in the structure of the living molecule, and are necessary to its normal reactions or irritability."

Now, given any disease attended by marked fever, the loss of the blood's main salt, sodium chloride, is not replaced, owing to restricted diet, anorexia, and the many factors which cause the patient to reduce greatly the intake of his normal food. At least one-half ounce of sodium chloride being voided daily in the urine, the time soon comes when the cells are hampered in their vital functions and gradually cease to secrete their autoprotective antibodies, thus giving free sway to the pathogenic elements. In pneumonia, especially, the cells hold their sodium chloride in reserve and the salt soon ceases to appear in the urine. But watch these cases; notwithstanding nature's attempt to thwart a desperate situation the patient steadily sinks, deprived of that which represents in this connection their pabulum vitæ. This summarizes Sajous' teachings when he wrote: "Steadily as the febrile process advances, the salts are consumed, and being inadequately renewed, the vital and defensive functions are increasingly hampered until life ceases." He, thereupon advised the use of saline solution, not when the case has reached the danger limit, but from the outset, at the start of all fevers, so as to avoid any chance of reaching that advanced danger limit.

Is there any connection between a febrile process and the blood-salts? To show that there is I will again quote a book published since the above teachings were placed on record; namely, the second edition of Lazarus Barlow's "General Pathology," 1905. Referring to the diminution of the blood alkalinity during fever, the author says: "The cause of this change is quite unknown, but whatever the true explanation may be, it is probable that the change is highly important for the organism, for it is an unfavorable sign in febrile disease, and it is known that dim-

*Read in the Symposium on Pneumonia before the Medical Association of the Greater City of New York, December 11, 1905.

inished alkalinity of the blood goes hand in hand with increased susceptibility to infection." Sajous had already advanced considerable experimental evidence to the same effect, including that contributed by Metchnikoff, Behring, Nissen, Paul, von Fodor, Blumenthal, and many other authorities.

Limiting my remarks to the subject of the evening, pneumonia, including the bronchopneumonia of children, since my work brings me much in contact with this dangerous form of the disease, I will cite as typical instance a case treated in my service only last week, that of a child seven months old, in which the characteristic signs of double extensive bronchopneumonia were prominent, with a temperature of 103.5° F. The use of saline solution alone produced such a prompt disappearance of the morbid phenomena that in seventy-two hours the child was practically well. Can this be attributed merely to crisis? The experience of others and myself in other cases, shows that such cannot be the case. On the old plea of washing out the blood—"hematocatharsis"—Lemaire[5] injected daily in children three years of age and over, 200 c.c. of a 7. per mille solution at one time and in children under that age 180 c.c. daily, divided into three injections. But he did not wait until the cases had reached the "desperate" stage; he initiated it as soon as the usual remedies had failed to produce the desired effect; when, in other words, the cases were not too far advanced. In the eleven cases reported, the blood pressure was promptly raised, diuresis was increased, the whole organism, notably the nervous system, was powerfully stimulated, oxidation was enhanced and all recovered. In such cases, there is a rise of temperature which may persist a few hours, then rapid improvement follows. The old view that the toxins are washed out of the blood is no longer acceptable, however, since Bosc and Vedel[6] instead of finding the urine toxic, found it hypotoxic—evidence that the toxins had been destroyed in the blood.

In adults the use of saline solution, even in desperate cases as advocated by Henry, Penrose, Tyson, may be followed by a sudden onset of convalescence. This affords evident proof of its power and indicates how greatly the chances of success would be increased if it were used before the danger period.

This is emphasized by the same line of reasoning that the six cases of Lemaire sustain. Bassi[7] also used the saline solution in six cases of grave double pneumonia in which the pulse already showed intermittence only the day before the expected crisis, and lost but one. Wherever, in short, the records on the subject afford any suggestion that the measure was resorted to somewhat earlier, even in severe cases, the chances appear to have been increased. In Henry's series the deaths were one in four, in Penrose's one in three, in Bassi's they were one in six, etc. Recently J. B. Todd[8] introduced a measure which will serve greatly to facilitate the use of saline solution; *i. e.* administering by the mouth as a lemonade, each glassful (six to eight ounces) containing ten grains of sodium chloride and five grains of potassium bicarbonate and a teaspoonful of lemon juice. This is given every two hours in adults. In the two cases reported among those thus treated, one of woman of 84 years and the other a girl of eight years, the temperature was 104° and 103 5° respectively when first seen. Saline drinks were instituted early, and produced the typical effects of intravenous and subcutaneous injections, both ending in recovery.

These few examples will serve to illustrate the aim in view. It is a new line of thought which awaits development through the teachings of general experience, but what little has been done backed by the solid experimental evidence to which I have briefly referred, is already full of promise. How far-reaching this line of thought may prove to be can be illustrated by a possible development which will surprise you as much as it did me, when Dr. Sajous pointed it out to me: We are looking on all sides for immunizing sera, which, like antitoxin in diphtheria, will enable us to cope with the great scourges of humanity, among which pneumonia is rapidly taking the lead. In the recent address to which I have already referred, Behring advances as a biological law that "specific immunizing substances can be obtained in no other way than from the blood and organic juices of individuals who have passed through the diseases against which we wish to produce immunity." Now, since saline solution can, as proven experimentally, maintain the blood's antitoxic properties, it can do so only by enabling these "blood and tissue juices" to act efficaciously and specifically, and, according to Sajous, the early use of saline solution, in all febrile infections must therefore produce the effects that we are trying to obtain from specific sera. Especially will this become a life-saving measure when his view that the blood's immunizing antibodies can be increased by judicious medication will have been as clearly demonstrated to the profession at large as it has to those who have put his teachings to the test.

Addendum.—Dr. Homer Wakefield of New York has sent me the following remarks forming the substance of what he had intended to say in the discussion of this paper. The lateness of the hour, however, cut short the general discussion.

"Dr. Taylor's paper involves many interesting chemical aspects of pneumonia. In addition to the relation of sodium chloride to the osmotic pressure, which is unimportant in the higher animals, owing to the many other factors which influence the density of protoplasm and thus vary the osmotic equilibrium, and therefore disturb the equilibrium with its media, sodium chloride undoubtedly plays a part in the maintenance of the alkalescence of the blood, and still more important are the halogen properties of catalysis, and the bivalency of chemical constitution of chlorine, by virtue of which, as is well known, it is a sort of prototype of oxygen. Possibly it is owing to an oscillatory attunement, that oxidation is so intimately related to the bivalent elements. The halogens are the salient catalytic factors of sea water, and probably also of the blood, where we know they play at least an important subordinate rôle.

"In pneumonia, where we have to deal with a pulmonary acidosis, as determined by the researches of Rosenow of Chicago, depending on the acid products of the diplococcus, we know we have a condition of *sub*oxidation, owing to the impossible condition of acidity, and the morphology of the sequence of the process, which precludes oxygenation to the involved areas. Now we know that in the laboratory, under conditions favorable to oxidation, but in which oxygen is practically absent, and chlorine is present, the chlorine enters the combination in place of oxygen. In other words, oxygen affinities, in the absence of oxygen, exert their attractions for chlorine, which, if present, would be extracted from less powerful combinations, and thus they are bound by the asphyxiated tissues. It is evident that such a procedure would withdraw the chlorides from the blood, during

the oxidation period, which is exactly what happens in pneumonia. It is interesting, in support of this hypothesis, that complementary to the hastening of resolution of pneumonia by administered chlorides, is the equally successful method of Dr. Frank Billings of Chicago, who is enthusiastic over his alkaline treatment, and Altshul of New York, who has found potassium iodide almost a specific.

"The additional fact that chlorides are retained in diseases of suboxidation, other than pneumonia, is confirmatory of the theory of the displacement of oxygen by chlorine in these cases.

"Next we are brought to a consideration of the relation of chlorides and oxidation to toxins and antitoxins. We have not time to discuss this profound subject, but suffice it to say that recent advances in physical chemistry, coupled with some physiological researches, have pretty well established the fact that antitoxins are electrochemical opposites of toxins, and are producible from toxins, in the economy and in the laboratory, by the catalytic action of oxidation, electricity (especially high frequency currents), Roentgen and Bequerel rays, etc. Such being the case, we can readily appreciate the overaccumulation and greater toxicity of poisons during periods of suboxidation, and the recuperation of antitoxin production on restoration of oxidation.

"Theories of disease, which are capable of a very restricted application, are generally weak. Conversely, when universally true, they are generally confirmed by collateral truths, often obtained in widely different fields. Such is the case with Dr. Taylor's contributions to pneumonia; they are entirely compatible with my own findings."

AN INQUIRY INTO THE SCIENTIFIC PRINCIPLES WHICH UNDERLIE THE MILK FEEDING OF INFANTS.*

By THOMAS S. SOUTHWORTH, M.D.,

NEW YORK.

ATTENDING PHYSICIAN, NURSERY AND CHILD'S HOSPITAL, NEW YORK CITY CHILDREN'S HOSPITALS AND SCHOOLS, PHYSICIAN OUT-PATIENT DEPARTMENT BABIES' HOSPITAL.

The question of the substitute feeding of infants has assumed such importance both in the family and the state, and the views which are held upon this subject have become so diverse, that if we are to satisfy an increasingly intelligent laity we should be able to demonstrate clearly the fundamental principles upon which such feeding rests. Despite the fact that empiricism has heretofore been our main reliance, I believe that there is such a thing as the *science* of infant feeding, and that this, like all other true sciences, is demonstrable. It may, therefore, prove of interest to enter upon an inquiry as to why cow's milk, aside from its cheapness and availability, constitutes the best substitute food for infants.

Animal bodies are made up of certain basic principles: Fat, proteids, carbohydrates, mineral salts, and water. This applies to all higher animals, old and young, and the human infant does not constitute an exception to this rule. These elements, which go to make up the body, must be furnished in the food. They are found in very diverse forms of food, such as hay, grass, grains, vegetable matter, milk, and flesh. But the inherent differences in these types of food show us that we must go back beyond their gross chemical composition if we are to understand their ready utilization by the animal. To-day anatomy and physiology have come to be more fully recognized as intimately associated and complementary subjects than was the case not so very long ago. We recognize that form is adapted to function, and the expert will readily deduce structure from function, or function from structure, in studying extinct or existing forms of life. He will tell from the teeth whether an animal was carnivorous or herbivorous, and its type; from the legs whether or not it was suited for speed in escaping its enemies; and from other portions of its structure whether it was adapted for attack or defense.

From structure and function it is an easy step to certain gross relations between the food and the structure and functions. The foods of different animals are not alike, and their digestive tracts are not the same, but even those which eat the same kinds of food show distinct variations, depending upon their types of digestion. Twenty pounds of hay furnish but one pound of proteid, while one pound of lean flesh contains approximately one-fourth pound of absolute proteid. The hay-eating cow requires, therefore, a larger digestive tract, with provision for bulky foods, the carnivorous wolf a much smaller one. In the ruminant herbivora like the cow, who rechew their food, the stomachic portion of the digestive tract greatly predominates in size. In non-ruminants, like the horse, whose food is finely divided before swallowing, the stomach is very small and the intestinal portion, especially the cecum, enormously developed.

We have thus far spoken only of the adult mammal, to establish the fact that its digestive tract is adapted to its peculiar food and its type of digestion, and you may readily be inclined to ask what bearing this has upon the question of milk. In some of the lowest forms of animal life, like the ameba, reproduction is brought about by a constriction of a part of the parent body and the gradual separation of a complete organism capable of independent existence. At the other extreme of animal life we find the highly developed human being. When an infant is separated from the human mother's body, nutrition has for some time been carried on by the placental circulation. After anatomical separation from the mother at birth, the nutrition is still derived from another part of the maternal body, the breasts, and a physiological connection or dependence still continues. In the prenatal state, evolution of the fetus has only advanced to a certain point. After birth coordinated use of the limbs is still to be acquired; the teeth, the powers of digestion, and the brain are still undeveloped. With most mammals, when maternal feeding ceases the structure is completed and physiologically ready for independent existence, although often requiring some degree of care and protection. Maternal feeding, therefore, may be said to be practically continuous from conception to weaning. During the mammary period of maternal feeding the mother has still to furnish to her offspring the five great food principles: fat, proteid, carbohydrates, mineral salts, and water. These are now furnished in the form of milk. Only when the digestion and the teeth have been developed do the ordinary rules of dietetics apply to the child, as everyone who has attempted

*Read at the annual meeting of the Alumni Association of St. Luke's Hospital, April 14, 1905.

to feed infants knows. There is as much difference between the types of food consumed by the infant and the adult as there is between those consumed by the dog and the horse. All require the same elementary food principles, but require them in decidedly different forms. The fact that about one year after birth the child can thrive on food which at birth would cause its death, shows that a complete change has taken place in the digestive tract. What is true of the infant is true of the calf and other suckling young. It is evident, therefore, that the nutriment furnished to the young is fitted to a digestion which is undergoing continual change. The food is the same, but the digestive powers are changing. This brings us to the true basal problem of infant feeding, namely, how milk whose composition and properties remain practically the same throughout lactation can be equally suitable for a digestion that is at birth feeble and at weaning able to care for solid foods. The explanation is a simple one, although it has only recently been advanced. It is that the milk itself is directly instrumental in developing the digestive tract.

That all milks are foods needs no demonstration. The world has long recognized that there were certain gross differences between woman's, cow's, mare's, and goat's milk, although it has regarded them as much the same. The chemist has shown us that they all contain fat, proteid, sugar, mineral salts, and water, but that these are present in different proportions. These quantitative differences in composition are readily explained by the fact that those species of young which grow most rapidly require more structural material. The problem of feeding the young of one species with the milk of another species would be a simple one were these quantitative differences of the elements the only ones, but when these are adjusted, other differences which are qualitative remain. What explanation, then, can be found for these qualitative differences, which are especially marked in the proteids and more specifically in the caseins of different milks? For this purpose we must inquire into the processes which take place during the digestion of milk. The digestion of the infant or young animal has been looked upon largely as that of a small-sized adult. But if that were true, the young should be able to digest proportionately small quantities of adult food. A little thought and observation will show that from conception to weaning the nutritional problem is complicated by the continual evolution of form and function; while from weaning to the adult stage increase in size and strength are the principal changes. The question must be approached from the standpoint of the physiological dependence of the young upon the mother during lactation.

Immediately after birth the mammary glands do not secrete true milk, but colostrum, which also contains the five food elements, fat, proteids, sugar, mineral salts, and water. This is gradually replaced in a few days by true milk, which remains practically uniform throughout lactation. It would be manifestly difficult to study the gastric secretions of the new-born infant, but this can be done in the calf. In cheese-making large amounts of rennet are required, the chief available supply of which is from the stomach of the calf, from which it is extracted with brine. During the first few days after birth the yield is small and very inferior. In other words, during the period of colostrum, which differs from milk in its composition and properties and is not readily coagulated by rennet, the calf's stomach secretes but little rennet, but as the true milk appears rennet is secreted, and its function is to change a portion of the milk into a soft, semi-solid mass. Thus the young animal creates its first solid food from its mother's milk. Now, the true gastric secretion of adult animals contains in addition hydrochloric acid and pepsin, but these latter are practically absent in very young animals. Pepsin alone (without acid) will not digest the solid food produced by the action of rennet upon milk, so this soft clot passes into the intestine in a form suited for intestinal digestion. As the stomach develops, pepsin and acid are secreted, which would at first thought mean the digestion of this soft rennet clot with but little work for the digestive apparatus. But this is not the case, for a portion of this soft rennet clot combines with the acid and is changed into a denser curd which pepsin can attack. As larger quantities of acid and pepsin are secreted, the acid makes more of the curds requiring pepsin digestion, and with a still further increase of acid makes another yet denser form of curd, so that the amount of work for the stomach keeps pace with gastric secretion. It will not be difficult, with this explanation in mind, to understand why milk is peculiarly suited to the development of a digestive tract which is undergoing evolution.

Now, the stomach of the grown cow, which eats a coarse, bulky food, digests best when fully distended, and that the stomach of the calf is being developed to do the same is prettily shown beyond doubt by the fact that the cow's milk, which completely fills the stomach of the calf, is changed by the rennet of its stomach into a semi-solid of exactly the same volume.

A study of the milks of different species shows that their behavior in the stomachs of their young corresponds closely with the behavior of the adult food in the adult stomach. This is one of the fundamental principles which must be borne in mind in adapting food for young animals. All milks are nutritious and good foods, but just as the digestive tracts of the adults of the different species are not alike and their foods not interchangeable, so the digestive tracts of the young are not alike nor the milks, which are their foods, interchangeable. In short, one of the main problems in infant feeding is not only to select a food containing the proper basic elements to sustain life and supply material for growth, but also to furnish it in a form adapted to assist in the evolution going on in the digestive tract. Milk will of necessity be the basis of such a food, since there is no other similar substance which, while fulfilling all other requirements, will form a solid in the digestive tract under the action of the gastric secretions. No other animal gives a milk which even closely approximates human milk. The cow furnishes the most available supply, and our most intelligent efforts must be directed to making this over so as to be acceptable to an infant whose digestive tract is not at all that of the calf.

The stomach of the human adult is fitted for the digestion of well-divided food, which reaches the stomach after division by the teeth. Thorough mastication is recognized as a prerequisite for good digestion. One need not be highly imaginative, therefore, to grasp the fact that the human infant also requires a finely divided food, such as breast milk forms in the stomach, and that solid masses would cause disturbance. With our present knowledge of the effects produced by the various measures employed in preparing cow's milk for infant feeding, we can readily see that each has aimed to produce, by either mechanical or chemical means, an alteration of the character of the solid formed from cow's milk in the infant's stomach. Let us consider some of the most important of these in detail.

Mere dilution with plain water reduces the bulk

of the precipitated curd, although this is not very effective in subdividing the curd.

It has been extensively taught that breast milk is alkaline, while cow's milk is acid, and that therefore the addition of an alkali to the acid cow's milk is necessary to make it conform to the normally alkaline breast milk, but it is now proven that this is not the case, since breast milk is also acid, and, furthermore, that practice has not even conformed to the teaching. The fact is that casein, which is capable of combining with either alkalies or acids, is not acted upon by rennet and changed into a solid when combined with a sufficient amount of an alkali, such as lime water. Therefore a sufficient amount of an alkali added to cow's milk has the effect of inhibiting the formation of a solid until enough acid is secreted to combine with and practically remove the alkali.

Alkalies or antacids added to cow's milk have, then, the specific property of preventing immediate coagulation in large masses. They may make the masses more flocculent, or even allow the escape of some fluid milk into the intestine. While the use of a moderate amount of the alkali may not only be harmless, but even helpful in approximating the form of the curd of cow's milk to that of breast milk in the infant's stomach, it is an open question whether the ultimate results of the excessive or too prolonged use of alkalies may not be to retard the development of the stomach, which requires work upon soft solids to complete its evolution.

Again, in order to alter the character of the milk solids formed during digestion, certain gruels of barley, wheat, rice, or oatmeal are employed as diluents. These contain soft flocculent matter in suspension which, when dispersed through the milk, mechanically alter the curd and allow access of the digestive secretion to a larger surface. Peptonization was advanced because its action in transforming the casein into soluble and non-precipitable albuminous bodies lessened or totally prevented the formation of solid curd. Its continued use is open to the same objection as the use of excessive alkali, and the peptonizing powder itself contains an alkaline antacid, bicarbonate of sodium.

Yet again, it has been proposed to remove the solid casein from the milk by the use of rennet and to furnish the food in the form of whey. In this form little or no solid can be elaborated from the food during digestion. While many of the measures which limit the formation of solids have important fields in the emergencies and difficulties of infant feeding they are edged tools capable of doing ultimate harm unless used intelligently and conservatively.

Having established the fact that the digestive organs of the different species are not the same, and that the maternal milk of each species is especially adapted to the rapidity of body growth and to the development of the digestive tract of its own young, we may well inquire before attempting to adapt the peculiar food of the calf to the requirements of the human infant what are the special functions subserved in the economy by the various elements of milk, namely, fats, proteids, sugar, mineral salts, and water. Proteid is a builder and a repairer of tissue, and of the blood also, since the blood is a liquid tissue, living cells in a fluid stroma. Fat also has a place as a tissue builder, although within limits, one of less vital importance. It is chiefly oxydized to produce heat. The principal function of sugar and of starch, which is closely allied to it, both being grouped as carbohydrates, is to supply heat and energy. The popular idea of the addition of sugar to diluted cow's milk is that it sweetens it and renders it more appetizing for the child. The carbohydrates are really fuel foods containing carbon (charcoal) chemically combined with water, and their sole food value lies in the energy derived from the carbon which they contain. This is readily demonstrated by dehydrating sugar by adding sulphuric acid (H_2SO_4), which itself contains no carbon but has so strong an affinity for water that it withdraws it from chemical combination and leaves free carbon.

One of our chief concerns in providing a substitute food for an infant must be to provide a well-balanced ration. The elements must be furnished in certain relative proportions. Material for the production of energy must be provided for. This should be derived from carbon, and if not supplied in the form of carbohydrates, the fat and proteid of the food will be called on to furnish the fuel and their utilization for growth will be prevented. If, however, the fat and proteid in the food are still insufficient, the tissues of the body itself will be attacked, with actual loss of body weight. Therefore the first requisite is to give enough sugar (carbohydrate) in the food to spare the fat and proteid for the performance of their own proper functions. Next in importance is the giving of adequate proteid to supply enough building material for the proper construction and development of all parts of the organism. Unfortunately it is the proteid of cow's milk which forms especially dense solid masses in the infant's stomach, and if difficulty is experienced in their digestion, the temptation is to reduce the amount of proteid in order to overcome the indigestion. If this is done and an excess of sugar furnished, as in the giving of dilute sweetened condensed milk, the infant may still show apparent growth by reason of the production of fat, since fat may be formed from carbohydrates. The scales would then perhaps show a proper weight, but blood and physical examinations would show anemia and poor muscular development. Finally, a certain amount of fat is needed in the normal food, but there is less danger in the underfeeding of fat than in underfeeding of proteid, and the amount required by different children is most variable. The best results are naturally obtained from a proper relation of all the elements in the food.

We have endeavored from the study of the analysis of human milk to determine what these relations are, and from these and our clinical experience have found that certain percentages of the elements are in general necessary for well-rounded development, and that while individuals vary much in their tolerance and powers of assimilation, any wide variations from these standards, too long continued, are attended with grave results, which may, however, be so slow in revealing themselves that their true causes may perhaps never be recognized unless this principle is remembered. Reduced to a few words, this fundamental principle may be stated as follows: The food of the infant should contain a sufficient amount of carbohydrates and fat to maintain the vital processes and prevent the proteids of the food from being called upon for this purpose. The proteid should be spared not alone for the repair of tissue waste as in the adult, but to promote the growth and the building of new cells, since young animals retain in their tissues about 70 per cent. of the digested proteid of a normal diet. The amount of proteid in the food must be gradually increased beyond the minimum safety point with which it is necessary to begin, in order not to overtax the digestion with this less readily digested casein of cow's milk. At the same time we may lay down the axiom that the bulk of the proteid in an

infant's food must be derived from the casein of cow's milk because such milk proteid is alone capable of producing a gradually increasing tone of the stomach. The measures adopted to secure the digestion by the infant of a sufficient amount of the casein of cow's milk to maintain the tissues and promote growth will have to be decided by the physician for each individual infant, and the art of infant feeding as distinguished from the science of infant feeding, with which this paper deals, is principally wrapped up in this one point. It is for the physician to determine: whether beside dilution with water he will make such alkaline addition to the milk that it will remain in a flocculent or semifluid state; whether by the freer use of some alkaline antacid like bicarbonate of sodium he will completely neutralize the acid of the stomach and throw the digestion of the food into the intestine; whether he will use a gruel diluent to mechanically separate the milk curd; whether he will combine several of these measures; or whether perchance, in cases of particularly difficult casein digestion, he will stop milk entirely and temporarily feed some food which will not form a solid in the stomach.

807 Madison Avenue.

OBSTRUCTION OF THE PYLORUS.*

By ROBERT HURTIN HALSEY, A.M. M.D.,
NEW YORK.

In the past few months many excellent articles, written by notable men and dealing with some particular forms of obstruction of the pylorus, have appeared in the medical magazines. You have doubtless read these, and it would indeed be presumptuous to bring up for discussion what might seem to be a repetition of recent literature. What is here presented has been drawn from new sources, for it is based upon cases of obstruction which it has been my good fortune to have the opportunity to study. The cases have been observed in the hospital service or in the private practice of Dr. Quintard, and I wish to acknowledge at this time my indebtedness to him for permission to refer to them.

To read the full histories of these cases would be tiresome, but certain details of the histories and physical and clinical examinations are interesting, because unusual, and these have been selected. Though the number of cases in the series is too small to draw any general conclusions, yet they furnish material for discussion, which is our purpose in presenting them at this time.

Case I.—A young nurse of 32 years of age. When she was 16 or 17 years of age she had more or less stomach trouble, which consisted of dull aching one or two hours after meals. It was never unbearable, nor did she suffer from headache or vomiting. In the practice of her profession she had many trying cases, and in other ways was under considerable mental strain, but with frequent vacations managed to live along in fair health until August, 1904. At that time she began to notice that she had considerable gas in the stomach and a sour, burning sensation in the throat. Both of these conditions were worse toward night, but there was neither nausea nor vomiting. In November, 1904, after eating a pickle with her meal, she had considerable distress and vomited a large amount of food and fluid. She remained in bed for two days and took only a light diet, washing out the stomach every other day. No food remnants were found until a month later.

The sour condition and smarting in the throat continued with more or less severity until the following March, but there was no vomiting. During this month she frequently suffered from "water brash," and would make herself vomit for relief of distress in stomach. The bicarbonate of sodium, which she took to relieve her, she said would "sizzle" as she swallowed it.

She came under observation in April, 1905. Passing the tube at this time into what should have been an empty stomach brought up with marked expulsive force 1,500 c.c. of food. Several meals given subsequently showed a very high acidity—free HCl 36-48 in a total acidity of 52-72—and numerous sarcinæ. The total quantity of return varied in amount from 300 c.c. to over 1,000 c.c. On examination of the abdomen no splash was heard, no visible peristalsis or distension of the stomach was present, nor was a tumor or area of tenderness found. The blood and urinary analyses were negative.

She was kept in bed without food by mouth for three days. Every eight hours during these days she received a nutritive enema. After the fourth day she was given a little broth by mouth, every twelve hours. The frequency and amount of these feedings were gradually increased, so that at the end of two weeks she could take some solid food. Lavage of the stomach with a solution of silver nitrate (1-5,000) was done once daily at first, and less frequently later.

A complete recovery followed and has been maintained. It would seem in this case as though a tumefaction secondary to a gastritis, with a high acid production, was the cause of the obstruction. The happy outcome without resort to surgery indicates that the treatment of certain forms of obstruction will yield to rational therapeutics.

Case II.—A single woman, 24 years of age, thirteen months before admission to the hospital had had an open operation for appendicitis. During that period she had infrequent attacks of right-sided abdominal pain, followed by vomitnig of food. These attacks would occur soon after meals. As the attacks became more frequent in occurrence, a smaller quantity of food would produce vomiting, and, during the few weeks prior to observation, vomiting would follow the eating of a very small quantity. The severity of the pain, which was cramplike in character, was increased not only by eating, but even by assuming the erect position. These paroxysms could be relieved by lying down. Small amounts of fluids could be taken until a few days before admission, when food of any kind produced vomiting.

Examination showed tenderness over all the right half of the abdomen, with an area of greatest sensitiveness 8 cm. to the right of the umbilicus. No tumor could be felt. Examination of material from the stomach showed a high acidity. The study of the blood and urine did not indicate any abnormal condition, other than a reduced hemoglobin. The points of the history to notice are the open operation for appendicitis, and a subsequent gradual increase of obstructive symptoms, with general right-sided tenderness.

To relieve the symptoms an operation was undertaken by Dr. Lloyd, who found the greater curvature and pylorus of the distended stomach drawn over to the right side and adhering to the ascending colon. This amount of distortion made the outlet form an acute angle with the rest of the stomach, and as the duodenum still retained its normal relations, a second sharp angle was formed in that tube at the beginning of its second portion. In addition there was an adherent V-shaped turn in the ascending colon, midway between the caput and the hepatic flexure. These adhesions were broken up and

*Read at a meeting of the Section on Medicine of the New York Academy of Medicine, November 21, 1905.

the symptoms temporarily were completely relieved. Four weeks later, all the symptoms returning, Dr. Lloyd undertook a second operation, which revealed the formation of a new and similar condition of adhesions about the stomach. Again the adhesions were relieved, and, in addition, a gastro- and enteroenterostomy were done. Relief was permanent after this combination of operations.

The history and physical signs in connection with the condition discovered at operation make a complete picture of the gradual progressive changes adhesions may bring about in the position of the stomach. Sedatives and lavage, while they relieved the symptoms in the early stage, naturally could not cure the condition, while an operation alone, as finally performed, did give complete relief from further trouble.

Case III.—A small woman, 34 years of age. She dates her trouble from 1898, when she was treated here in New York for a supposed attack of gall-stones (whatever that may be), which it was claimed had been dissolved out of the gall-bladder by the use of olive oil and milk. Continuing long after the time a cure was declared, she had a variety of symptoms which were classed as "indigestion." In the latter months of 1902 the distress after eating was so severe as to compel her to restrict herself to soft or fluid diet. After taking moderate amounts of solid food, cramping pain always preceded the vomiting, which relieved her. Even a large amount of soft or fluid food would cause her the same distress when first taken, but afterward the intensity would gradually diminish. As the amount and character of the food changed, her general nutrition suffered, so that when she came under observation she weighed but fifty-seven pounds, which indicated a loss of forty pounds.

No tumor could be felt, nor was there any tenderness. The signs of obstruction of the pylorus were evident, and on testing the caliber it was found to be so diminished that koumyss would not pass out, though water or milk with an equal amount of vichy would. The blood, urinary, and gastric analyses were negative.

To increase the caliber of the pylorus, Dr. Lloyd did a pyloroplastic operation of the Heineke-Nikulicz variety. The pylorus was found to be very much thickened and a probe could just pass through the lumen. The gall-bladder was found to be free from adhesions or a palpable calculus, and on this account the inference was drawn that the old attack of gall-stones was really an ulcer of the pylorus and the obstruction was the subsequent contraction of the cicatrix. In the absence of adhesions, pyloroplasty was preferred because disturbing least the natural relations of the stomach and intestines.

Case IV.—A working woman, 43 years of age, a native of Sweden. During the preceding ten years she had frequent periods of burning sensations in the stomach and sometimes attacks of severe pain which radiated toward the back beneath the left scapula. Often she would find relief by vomiting a large amount of material which she described as "coffee-ground like." There was no history of faintness or dizziness at any time, or any vomiting of red blood. After the attacks she could eat her usual meals. Two weeks before admission she had what she considered the worst attack, which was accompanied with distension of the abdomen. She was very thirsty and hungry, but the pain was aggravated so much by either food or drink that her craving went unsatisfied most of the time. But finally, as she was unable to eat or drink and the epigastric pain seemed to be increasing in severity, she sought relief at the hospital.

Examination of the abdomen at this time showed in the midepigastric region an ovoid tender tumor, 5 cm. in the long diameter, and moving with the respiration. To the left of this mass the peristaltic movements of the stomach were plainly visible. With a soft stomach tube a large quantity of foul-smelling, dark-colored fluid was removed. This contained free hydrochloric acid and numerous sarcinæ. Lavage was completed and bismuth and alkalies given. On the second day the tumor had diminished more than half, and it was less tender. As the tumor diminished in size it was hoped that the obstruction also would be relieved, but it did not appear to be affected in the slightest degree. She was losing flesh rapidly and to relieve her Dr. Willy Meyer operated, doing a gastro- and an enteroenterostomy. Exploration at the same time revealed at the pylorus a mass which seemed to be due to an old ulcer having perforated through the stomach and become walled off by adhesions. Unfortunately the condition of the patient was so feeble that she died on the third day after the operation, apparently from sheer inability to respond to stimulants or food.

Case V..—A German carriage-maker, 38 years old. His previous history was good until ten months before admission. During this period he suffered from gaseous distention of the stomach, with pain after meals, nausea, and sour taste, but he never vomited. In the last few weeks the pain, which seemed to be situated low down in the abdomen, was worse toward evening. He had lost thirty pounds of weight since the beginning of his trouble. The abdominal examination revealed an enlarged left lobe of the liver, and a distended stomach with active peristaltic movement. In the region of the pylorus an indefinable tender mass was to be felt.

Analysis of the blood and urine did not show anything important. Removal of the stomach contents and subsequent test meals showed absence of free hydrochloric acid, the presence of lactic acid and Oppler-Boas bacilli. He was losing strength very rapidly, and to relieve his condition a gastro- and enteroenterostomy was done by Dr. Lloyd. He failed to pick up, however, and died one week later. The condition found was adenocarcinoma of the pylorus.

Case VI.—A man, 52 years of age. He had always been well until three months before admission, when he first noticed he was losing weight. He declared that at that time he did not have any trouble with his meals, but that six weeks before admission he did begin to have distress after eating. This consisted at first of belching after meals. Soon, however, he had cramping pain to the right of and on a level with the umbilicus. This pain was distinctly more severe after meals and when the bowels were constipated. In the mornings of the last few weeks he would have nausea and retching, and, finally, he would vomit remnants of food which he had eaten on the preceding day, or several days before. During the three months he had lost thirty-seven pounds from his usual weight. In looking him over the distended stomach in active peristalsis was to be seen some 5 cm. below and to the right of the umbilicus. At this point also was found a sensitive, hard, freely movable tumor about the size of an egg. Blood and urinary analyses were negative. On passing the stomach tube, about 1,500 c.c. of foul-smelling, dark brown fluid was obtained. There was plenty of lactic acid and Oppler-Boas bacilli, but no free hydrochloric acid.

The stomach was thoroughly washed out and an Ewald test meal given the next morning, and examination of this showed lactic acid and Oppler-Boas bacilli. On the third day of the washing he

felt much improved and desired to go home. The next morning an Ewald meal revealed on examination the presence of free hydrochloric acid and neither lactic acid nor Oppler-Boas bacilli. The next day, and on several subsequent days, a test breakfast showed free hydrochloric acid varying from 18-25, combined hydrochloric varying from 16-18, and the total acidity varying from 50-70. There were no sarcinæ.

Operation was advised and accepted. Opening the abdomen, Dr. Lloyd found a cancer of the transverse colon, with adhesions to the pylorus, which was obstructed by the compression and distortion.

Case VII.—A man, 69 years of age, with a history of perfect health until some three months before observation. The obstructive signs came on rapidly and his loss of weight was considerable. The distended stomach in active peristalsis, but without a palpable tumor, was the result of the abdominal examination. The blood and urine analyses were negative. Examination of the stomach contents revealed free hydrochloric acid and sarcinæ. The starch digestion was complete—neither dextrin nor erythrodextrin were present.

Dr. Hartley did a gastro- and enteroenterostomy, which was followed by uneventful recovery. On exploration a new growth was found on the lesser curvature near the pylorus. The situation was too high in the abdomen to permit of palpation through the muscular wall. Since the operation there has been an absence of free hydrochloric acid and a very low total acidity.

To recapitulate—Here are seven cases of obstruction of the pylorus, four of which are benign and three malignant. The diagnosis of obstruction was made upon the results of the physical examination and the clinical tests of the motor function; the differential diagnosis as to the probable etiology was founded upon a careful study of the previous history of the individual. The results of the operative findings should help to indicate in future cases a solution of the problem previous to operation, and so aid in a choice of treatment. In the seven cases, six were operated upon and five of those operations were gastroenterostomies. Of the three cases which were benign in character, only one was suitable for a pyloroplasty. One case only of the seven was permanently relieved by medical treatment.

Examination of the Urine.—The amount passed in twenty-four hours is diminished, its specific gravity is increased, and the percentage of urea is high. Indican is present in large excess. The ratios of urea and uric acid, ethereal and mineral sulphates, urea and chlorides, may or may not be greatly disturbed, but are usually depressed.

Examination of the Blood.—The hemoglobin is usually diminished, but in the malignant conditions, while the absolute percentage is lower than normal, it is often higher than we would expect to find, judging by the appearance of the patient. The absolute and differential count of the erythrocytes and leucocytes shows nothing characteristic.

As Dr. Sondern says, we find on examination a better specimen of blood than expected, because the vomiting diminished the volume of fluid in the circulation. The diminished volume, or increased concentration, so to speak, accounts for the greater number of cells found in a cubic millimeter. At the same time this phenomenon can explain the great variation, sometimes observed from day to day, in the hemoglobin and numerical count.

In analyzing these cases, the following may be observed:

1. A history of digestive disturbance extending over several years accompanies the non-malignant conditions; while a perfect euphoria, followed by a few months of increasing difficulty, is associated with the malignant cases.

2. A stomach distended with food contents and in active peristalsis, has an obstruction at the outlet, whether a tumor can be felt or not.

3. An obstruction of the pylorus may be due to a tumor which can be felt in another than the right upper quadrant.

4. The presence of lactic acid and the Oppler-Boas bacillus must not be interpreted to indicate the presence of a cancer; nor, on the other hand, does the finding of free hydrochloric acid and sarcinæ contraindicate malignant disease.

5. Retention of food in the stomach can cause a suppression of the secretion of hydrochloric acid and permit the formation of lactic acid and the growth of Oppler-Boas bacilli.

6. The selection of treatment should depend upon the probable cause, as relief can be obtained in some cases without operation. In selecting the operation, pyloroplasty should have the preference when a choice is possible.

CLINICAL ASPECT OF RHEUMATIC ENDOCARDITIS.*

By James D. Morgan, M.D.,
Washington, D. C.
Physician to the Garfield, Emergency, and the Georgetown University Hospitals.

Just so much as clinical lectures are supplanting didactic lectures and are correspondingly doing more good in impressing the salient features of any disease both upon the students and the clinician, so it is becoming to be known and more appreciated by the laity, that the best and most successful results are obtained where a systematic examination of the case is made. The prejudice against hospital and institutional treatment is thus lessening every year and the public is fast learning that a medical school hospital with its open ward clinics is the best place for the correct handling and treatment of all difficult or obscure cases. It is rather surprising that, hampered as we often are by the neglect of a thorough examination of a case, we can empirically treat successfully so many cases. It is the old staff, the *vis medicatrix naturæ* or the phagocytes, which leads us out of the wilderness. There are none of us who, seeing results, do not wish that we sometimes had a little more foresight and less "hindsight." Although the ravages of rheumatism do not leave as wide a wake as some hemic disorders, yet each pabulum of complication and suffering lessened or removed renders the human organism stronger to combat its other enemies.

There has been no abatement for a long time in the indifference and careless haste with which we treat and dismiss our arthritic cases. Perhaps the sequelæ of several of my own bad cases are responsible for the paper this evening. To find out if I was the chief or only offender in this regard, I have searched the records of several of the hospitals of our city for the following information regarding rheumatic arthritis: (1) In what proportion of cases was the heart examined? (2) In what proportion was complaint made of the heart? (3) In what proportion was heart trouble found, when complaint was made? (4) In what proportion was heart trouble found when no complaint was made? (5) In what proportion was heart trouble found, when a foreign complaint was made?

*Read as "The Monthly Essay" before the Medical Society of District of Columbia, December 6, 1905.

To get at these different varying conditions required patient and exhaustive comparison of many rheumatic records. As the investigation had to be somewhat limited, only acute articular cases of rheumatism were sought, gonorrheal rheumatism being also excluded. All records relating to endocardial or valvular disease were gone over to determine their dependency or not on articular rheumatism.

Another line of investigation was started at the same time in my service at the Central Dispensary and Emergency Hospital, and this additional information was requested and recorded regarding all cases: (1) The condition of the heart valves of all rheumatic patients. (2) Has the patient had acute articular rheumatism, and at what age? (3) Has the patient complained of the heart?

One is utterly shocked and pained when taking up this investigation of the dependency of endocardial diseases upon rheumatism, to find how long the patient and the physician have both been unaware of any cardiac lesion. Patients will come for all variety of complaints, some closely and others very distantly connected with ailments of the heart, such as

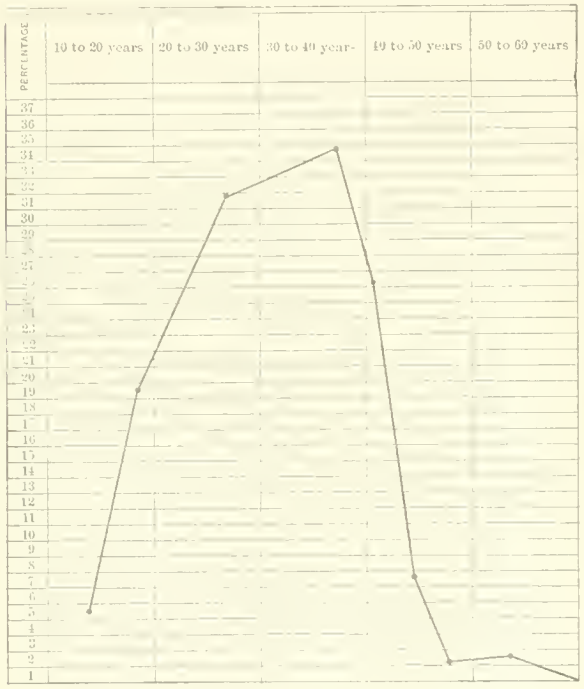

CHART 1.—Age at which acute rheumatism occurs.

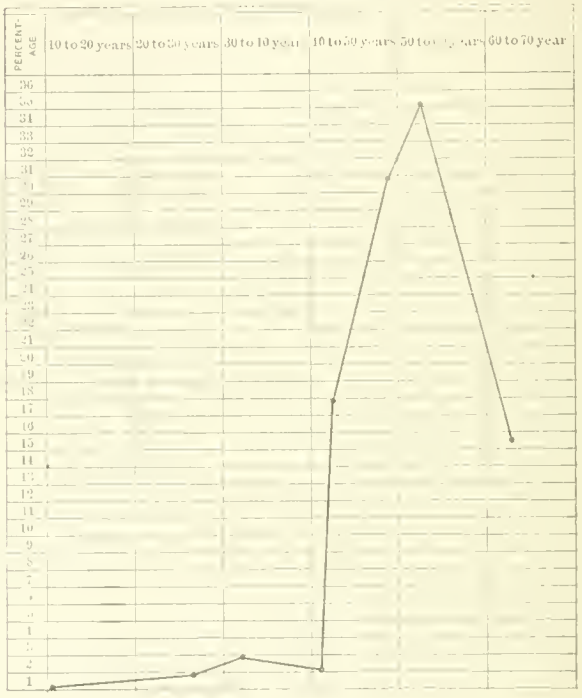

CHART 2.—Age when valvular disease is *discovered*.

dyspnea or vertigo, but the patient quite likely does not refer to his heart in any way and never mentions the antecedent attacks of rheumatism. It is a strange fact that in many of those patients who have had rheumatism and later on complained of the heart, no definite heart lesion could be found. Your experience may be somewhat akin to mine—that very extensive cardiac lesions may and do exist for years with no disabling consequence to the patient or giving evidence, without a careful physical examination, of the serious lesion which exists.

You will find that about fifteen per cent. of cases suffering from rheumatism were systematically examined; that about eighty per cent. of those examined, which includes acute and old rheumatics, showed heart lesions, that many of these eighty per cent. did not complain of the heart or mention their antecedent rheumatic attacks, but came to the dispensary or entered the hospital for such conditions as epilepsy, difficulty in swallowing, chronic bronchitis, dyspepsia, hemorrhoids, nervousness, etc. The proportion for heart lesions following first attacks of acute rheumatism is nearly fifty per cent. Hare gives a record of 842 cases, in 420 of which endocardial trouble was found, or fifty per cent. The attacks of articular rheumatism are most frequent between the ages of thirty and forty, and then twenty and thirty, but the valvular lesion is frequently not *discovered* until between fifty and sixty. In this series no cases of children under ten years are considered. Another point which seems of interest is, how few patients, proportionately speaking, of the whole number of cases in a general hospital are rheumatic cases; and how different it is in, and how it stands out in contrast to, a dispensary service, where a large proportion are complaining of or being treated for rheumatism. It tends to show that rheumatics do not retire until badly worsted and continue to do a good share of work for an indefinite period even with severe complications. Of 831 cases of all sorts treated at the Garfield Hospital Dispensary, only thirty were for rheumatism, or 3.72 per cent. At the Central Dispensary and Emergency Hospital, of 15,242 cases treated, of all sorts, 200 were for rheumatism, 103 being acute and 97 chronic and subacute, or 1.31 per cent; but when you consider the general medical clinic alone in which there were 1,562 cases, the percentage of rheumatism is 12.12 per cent.

Another interesting comparison shows that although there are three times as many women with rheumatism in the wards of the hospital, there is double the number of men seeking the dispensaries for rheumatism. The sterner sex being the breadwinner, cannot lay down so soon, but fights on with crutch and panting breath, a cold and clammy hand and brow, heavily waterlogged. The ratio of women in the hospital to those in the dispensary is as three to one; and in the case of men, the hospital population is to the dispensary as one is to two.

To show what college clinics do for a hospital or dispensary and indirectly, but which is more important, for the patient, student, and physician, a comparison for six months before clinics were organized shows five systematic examinations of the chest and heart and seventy-four problematical diagnoses; and for six months after clinics were established twenty-one systematic examinations and fifty-nine problematical, or the systematic increased four times as

the problematic fell off one-third. Among these cases examined were found fifteen with heart lesion and nine with no evident trouble following rheumatism, giving a percentage for valvular lesions of 9.2 per cent. for the 159 cases of general diseases examined in the medical clinic.

In twenty-six fatal cases of rheumatism, the location of the heart lesion, as determined at autopsy, was as follows: Mitral valve, 14; aortic valve, 6; both valves, 2; none, 4.

It needs no argument to convince you that all cases of acute articular rheumatism need rest, not only of the joint but, which is more important, of the heart. All autopsies show that the valve which has the most work is largely the first part to suffer; therefore lessen its tension and reduce the number of its contractions, help the excretions with copious draughts of water, alkalinize the secretions, limit the nitrogenous food, apply ice or sinapisms over the heart, use salicylates or, if they are depressing, salacin; a mixture with the iodides often protects the heart. I am firmly convinced that slight biliary stimulation, when the fever and the delirium and the heart run riot, is often of the greatest help. Remember that even a damaged and leaky valve has some power of rehabilitation and that the heart may for years continue to give very satisfactory compensation.

919 McPherson Square.

A NON-OPERATIVE METHOD OF TREATING PROSTATITIS.*

By WM. BENHAM SNOW, M.D.,
NEW YORK.

Inflammation of the prostate gland of various types and degrees has constituted one of the most distressing, most dreaded affections of advanced life in the male. Nor is it in advanced age only that prostatitis has blighted the life of the sufferer. There is no more baneful condition or more dejected sufferer than the sexual neurasthenic. What has been accomplished for these human wrecks in the past has been generally unsatisfactory to both the general practitioner and expert because no drug or local method of treatment except the employment of electricity has seemed effectively to relieve the local inflammatory process. The employment of electric currents has been looked upon with a degree of skepticism that was always relative to the want of knowledge of their employment and physiological effects.

Success in the treatment of numerous cases that have come under the writer's observation will warrant at this time the statement that in electricity we have a certain relief for all cases except those in which a malignant or tuberculous process is present, or cases in which fluctuation from the presence of pus is already present; the degree of success depending upon the amount of hyperplasia and degeneration that has taken place in the structure of the gland.

In the early stages of simple prostatitis the prognosis for an early and complete cure is uniform. In the later cases the abatement of the inflammatory process and the restoration to a normal condition relative to the degree of organic changes that have taken place is the certain result.

Prostatitis may be divided into acute, chronic, and complicated cases.

The acute cases may commence with an acute inflammatory process terminating in an abscess, or may be of slower progress accompanied with a large degree of infiltration and marked tenderness on manipulation.

The chronic cases of prostatitis are marked by a degree of lost function or inactivity of the gland, due to chronic congestion and infiltration going on gradually with the production of hyperplastic tissues in various degrees. In others the secretion becomes abnormal in character—ichorous and irritating. The fibroid type in which the development of the fibroid growth often extends into the bladder gradually encroaches upon and obstructs the urethral passage, increasing with age. The complicated cases may be associated with gonorrhea.

The Etiology.—In these cases there has been some irritating cause, usually arising from excesses, masturbation, or unnatural intercourse, but in many cases occurring without any evidence of a local cause. The pressure of hardened fecal matter against the exposed gland undoubtedly in some cases will set up an initial inflammatory process. Once instituted, it progresses as chronic inflammations usually do. Nature, unable to restore the conditions to normal, involves the structures of the gland in a chronic inflammatory process. It is the establishment of *stasis*. The old theory of the process of inflammation by which it is claimed that it is "nature's process of repair" seems to be contradicted in this as in most inflammatory conditions. If nature could increase the flow of blood to an inflamed part in just sufficient quantity to supply the demands for repair, an increased blood supply would be favorable to the restoration of the normal condition; but on the contrary, when an irritating or inflammatory process is once instituted, we have the establishment of a region of local congestion with stasis which tends to the institution of a chronic process of infiltration and later the development of hyperplastic tissues. When infection is present, however, this is beneficent, as it walls in the pus, but otherwise it establishes a chronic stasis.

Chronic inflammatory conditions result from nature's failure to overcome this condition, and so it is in prostatitis. The local infiltration and stagnation, which result from the establishment of the inflammatory process tends to a progressive hyperplasia in the gland with steady increase in size and the development of tissue, which, pressing forward upon the urethra, obstructs the urinary passage. This process in some cases extends to the vesical sphincter, producing such a degree of congestion and vesical irritation that the patient has frequent calls when the bladder is not distended. Other patients are very apt from neglect with overdistention, chronic obstruction or an indiscreet use of alcohol, to suffer from retention resulting in dilatation of the bladder leading to a subsequent presence of residual urine. The decomposition of the urine resulting from this condition induces a new pathological process which still further aggravates the suffering of the patient. Catarrhal cystitis and its accompaniments in a dilated bladder are the greatest obstacles to a complete cure of these patients, especially when it occurs in the aged.

The indication for the treatment of prostatitis of all except the infected and malignant types consists in the relief of the condition of local stasis and a restoration of circulation and the functions of the lymphatics and the other structures of the gland. The adoption of the method of stripping or manual massage and later vibratory massage and douching in the treatment of these cases has tended in a measure to relieve the condition. The failure to cure resulting from this plan of treatment, however, is due to the fact that the tissues, though relieved of

*Read before the Clinical Society of the New York School of Physical Therapeutics, May 19, 1905.

tension, are rendered relaxed and not restored to a tonic condition as they are by the high potential electric currents.

The *modus operandi* of the properly applied method induces contractions of the structures of the gland, the gland itself becoming intrinsically the means of relieving itself of infiltration and the other products of inflammation. Following this process a tonic circulation is restored throughout the gland, the fluid accumulations having been expelled. By this means the chronic process is overcome so far as is possible, always depending upon the degree of organic change that has taken place, which may impair forever the performance of some of its active functions. The process of inflammation will be abated and to that extent the local condition will be cured.

The prognosis in these cases will be relative to the degree of organic structural change that has taken place prior to the institution of treatment, the character of the inflammatory process as to infection or malignancy, and the management of the cases. It may be truthfully said in all cases where an inflammatory process has developed without the presence of pus or other infection or malignant process, the outcome of the treatment is certain of success. In aged men in whom the bladder is dilated with the consequent presence of residual urine, it will take considerable time and careful management to restore tone to the relaxed and dilated organ. In some cases, however, the condition disappears with the relief of the local inflammation. The hyperplasia will in the larger part persist, but the infiltration and other products of inflammation will be generally eliminated under skillful management.

The method of treatment I have employed in these cases is one fraught with absolutely no danger to the patient, but requiring a degree of painstaking attention to technique which is necessary to obtain the best results. For the benefit of those who are not familiar with the static wave-current and the employment of the vacuum tubes, which are the means used by the writer in the treatment of these cases, it should be made clear that the employment of the currents of the static machine effect in no wise electrolitically the tissues. The quantity or amperage of these currents is so small that no cauterant or electrolytic action is produced, the effect being purely mechanical. An electrode placed alongside any organic structure when this current is properly applied will induce contraction of its muscular and yellow elastic fibers. If the administration is regulated to a low rate of periodicity or interruption, which will allow pauses between the periods of contraction permitting a degree of relaxation during the process of treatment, the most favorable results will be obtained. In other words, if we employ a current in which the rate of interruption does not exceed 300 per minute, sufficient intervals will intervene between the impulses of contraction and the interruption, with relaxation, to produce more pronounced effects upon the inflammatory process than if higher rates of interruption are employed. The latter will hold the gland in a state of tonic contraction without permitting the intervals of relaxation.

The result of this plan of treatment is salutary, the effects of the treatment being most noticeable in an infiltrated gland after a judicious application of the current. The gland will become remarkably reduced in size and softened throughout the whole structure. If these administrations are made daily the condition will not relapse and the gland will be found each day smaller and softer, relative to the intensity or degree of congestion or infiltration present.

The length of spark-gap, which is the measure of the intensity of the action of the current upon the congested gland, must be regulated to meet the indications of each particular case. In the acute congestive condition where pus is not present, but an abscess pending, the application of the current to the gland will cause severe pain, when the spark-gap is even less than an inch in length, which is occasioned by the contraction of the inflamed tissues. In these cases, during the administration, which should usually be for twenty minutes, the spark-gap may be gradually lengthened as the cessation of pain permits. At the close of an administration under these conditions a spark-gap of two and one-half to four inches will be administered without causing pain, because the tissues have been disengorged and the pressure diminished.

When the static wave-current is used in the treatment of these cases, the positive pole should be connected to the electrode and the negative pole directly to the earth by a metallic path. The writer's method is to administer the current to the patient while lying upon his side, and holding the electrode with his hand, firmly (but not with too much force) against the gland. It may be held in place in this way or with an *x*-ray tube holder, the electrode being thus held in a fixed position against the gland. It is generally better, however, to educate the patient to hold the electrode in just the right position with the hand during the administration. The treatment may also be administered, in lieu of a properly constructed chair, with an electrode designed by the writer, upon which the patient may sit, the electrode being inclined forward to just the right degree and held in position by a properly adjusted cushion. This method, however, is not nearly so certain or practical as the method employed with the patient lying upon the side.

In the subacute cases it is possible to use a spark-gap of greater length at the outset, but in the writer's experience the length of the spark-gap should never exceed four inches, and as a rule two and one-half to three inches is sufficient. This will be usually penetrating enough to affect the deeper structures of a very much hypertrophied gland. The amplitude of the current which marks the depth to which contraction will take place is measured by the length of the spark-gap.

The promptness with which relief follows in these cases, and the extent of it, is surprising to those who are not familiar with the method. The applications should be made daily in most cases for the first ten days, and in some should be continued daily for a longer period. The administration in the milder cases will be sufficient if made for but ten or fifteen minutes. It is a noticeable fact that these administrations greatly accelerate or increase the activity of the glandular functions and produce a degree of increased excitement in many cases which call for a diminished frequency of administration and shorter application of the current.

The static wave-current administered, as it should be, from the positive side of the machine, the negative being grounded, is *par excellence* the best electrical modality for the treatment of prostatitis, though probably in many instances equally good results may be obtained by the employment of a properly adjusted vacuum tube connected directly from the positive side of the static machine.

The metal electrodes employed with the wave-current may be of various designs, according to the shape of the gland. In the writer's experience, how-

ever, the straight rectal electrode shown in Figure 1 has been found to be the most readily adapted and practical in a large variety of cases. The electrode

Fig. 1.

is usually passed in so that the bulbous portion lies with its convexity against the upper end of the gland and should be held in contact between the two lobes. It is not necessary that a large part of the gland be brought in contact with the electrode, the whole gland being thrown into contraction when the spark-gap is of sufficient length. A rapid discharge produces a tonic, steady contraction, while the lower rates of interruption induce a distinct vibratory or pulsatory sensation in the gland.

The electrode shown in Figure 2 will come in contact with more of the surface of the gland and is curved on the upper extremity so that it will reach

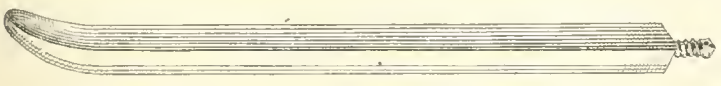

Fig. 2.

over its upper portion, coming in contact with the gland above. The straight electrode shown in Figure 3 may be preferred in some cases, though on general principles one either in the form of Figure 1 or having the curved extremity—Figure 2—is better adapted to the conditions present. Where it is desirable to make an application to the vesicles, the electrode should be carried up in contact and pressed

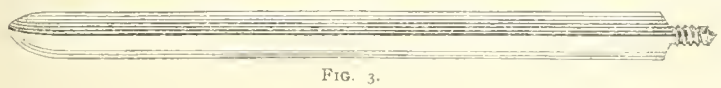

Fig. 3.

forward against the vesicles, when it is apt to be held away from the prostate if the patient holds it with the anus as a fulcrum.

The vacuum tubes employed are the ordinary glass hemorrhoidal tubes shown in Figure 4, which serve an excellent purpose for the treatment of prostatitis, though in some cases they may not be long enough, and it may be better to employ the curved electrode which may or may not be insulated where it passes through the anus. Another glass electrode made, having an anterior curved surface, may also be employed in the treatment of this affection. It does not seem to matter what sort of electrode is used, provided enough current strength is employed

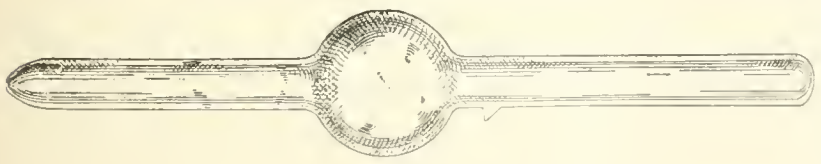

Fig. 4.

to produce a tonic vibratory effect, inducing contraction of the tissues of the affected gland. Other electrodes may be used on the urethral side of the gland, for which the ordinary metallic sound, having a wire attached to the upper extremity and held in position by the hand, serves an excellent purpose.

Vacuum electrodes, made in the shape of urethral sounds, may also be employed in cases having considerable irritation in the urethra, producing a remarkable degree of relief. The vacuum tube administration should not exceed ten minutes and should be applied directly from the static machine (positive side—negative grounded) as when applied for the rectal treatment. The application of the vacuum tubes directly from the machine when the spark-gap is long enough induces a distinct vibratory effect associated with the tissue contraction. This effect with the vacuum tubes has not the same characteristics from any other source of current, or when administered in any other way.

The writer's attention was first called to the value of these currents in the treatment of prostatitis when treating a case of neuritis in which the lesion was located in the pelvis. An examination of the rectum showed a very much enlarged prostate gland. A metal electrode was placed high in the rectum with a view to relieving the neuritis, and incidentally the gland was very much reduced in size and softened after the first administration. This suggested its employment in other cases and led to the present method of treatment, which has been in use by the writer and others for the past five years. During this period the writer has treated about 40 cases of all classes and conditions in patients of different ages, and in no case has there been a failure to produce some degree of improvement. In 75 per cent. of the cases treated there has been a complete relief from the symptoms and a cessation of the disposition to relapse. A few cases will illustrate the method of treatment and the usual result obtained.

Case I.—Mr. G., aged 63, called May, 1901. The patient came under observation suffering from a severe cystitis associated with a marked enlargement of the prostate gland, with almost complete obstruction of the urethra. For four years the patient had been obliged to rise three or four times every night, and during the month preceding the institution of treatment had not retired at all, from the fact that he would be compelled constantly to rise to void his urine. He was referred by the writer to a specialist for examination and treatment. Internal medication was prescribed, but gave him no relief. At the end of two weeks he returned, stating that if something was not done he would feel compelled to destroy himself, as he could not live in that condition. Previous experience suggested the administration of the wave-current, which was applied with the straight rectal electrode previously described, held by the patient against the prostate gland. From the institution of the treatment the relief was marked. Administrations were given daily for the first ten days, and then every second day to the end of the third week, at which time there was absolutely no tenderness. The gland was greatly reduced in size and the patient had ceased to be called upon to rise at night and was voiding his urine with comparative ease. Treatment was then discontinued and he has since remained well without the necessity of rising at night.

Case II.—Mr. B., age 32, railroad switchman by occupation, had suffered for five years with pain over the sacrum and extending down the inner side of the thighs, also with a feeling of depression and dejection, together with marked impairment of the sexual functions. The patient called in June, 1902. At the first examination the prostate was very much enlarged and so tender that the first contact of the examining finger caused severe pain. The straight rectal electrode shown in Figure 1 was

placed in position and held by the patient, who was treated lying upon his side. The wave-current was administered for twenty minutes. At the commencement the spark-gap was opened one inch, and caused such severe pain that it was necessary to shorten it considerably. During the twenty minutes of the administration the discharging rods were gradually separated so that at the close the spark-gap was fully three inches. The sense of relief which followed the administration was remarkable, the gland having been reduced fully one-third in size and very much softened throughout its whole substance. The same application was made daily for one week, at the end of which time the patient had made remarkable improvement, the gland having been reduced to nearly normal and being not at all painful upon examination. The treatments were then continued every second day for another week, at which time the patient was discharged, and there has been no recurrence to the present time.

These cases illustrate the results in the most difficult stages and conditions of the affection, and are cited for this reason. Other cases of the same type and class have responded with the same degree of uniformity and lead to the following conclusions:

1. Where simple congestion is present in the early stages of the affection the relief is prompt.

2. When the gland has been enlarged for a number of years with resulting infiltration and development of vesical irritation and obstruction of the urethral passage, the lesion is capable of being abated and the congestion relieved with the absorption of infiltrated exudates, the hyperplastic tissue only remaining.

3. In the aged, in whom the gland has become greatly enlarged, and is dense and hard from the growth of hyperplastic fibroid tissue, the inflammatory process will be abated, affording a degree of relief to the obstruction commensurate with the site and extent of the inflammatory process. The dilatation of the bladder which has intervened may be greatly relieved and cured in most cases by the persistent application of the electrical current over the pubis and by an electrode carried high into the rectum and pressed forward against the bladder, together with judicious washing of the bladder and the use of strychnine. The current applied in this manner induces temporarily contraction of the muscular coats, and finally restores sufficient tone to enable the organ completely to empty itself.

The perfect result when dilatation has intervened will depend upon the chronicity, and the patient's capacity for recuperation. The complicating seminal vesiculitis in these cases is successfully treated in the same manner, restoring a normal condition and function and relieving the irritation induced thereby.

These results, which have been obtained in the succession of cases which have come under the writer's observation, lead him to urge at least a thorough trial of the method by others. A measure which is as purely mechanical as massage offers no element of danger. The technique is simple and the method has been successful.

A NEW METHOD OF TREATMENT OF ACNE.

PRELIMINARY REPORT.

By ELI MOSCHCOWITZ, M.D.,

NEW YORK.

This method consists in the application of the well-known principle of Bier, in the treatment of inflammatory processes by inducing hyperemia. The value of hyperemia as a curative agent in acute suppurations was announced by Bier early this year, in the *Münchener medizinische Wochenschrift*, Nos. 5, 6, and 7, 1905. In his earlier efforts, hyperemia was obtained by the use of the Martin bandage applied proximally to the inflammatory focus. More recently his assistant, Klapp, has demonstrated that a local hyperemia limited to the inflammatory process may be obtained by the use of various forms of dry cups; this is especially applicable in localized suppurations of the soft parts, such as circumscribed abscesses, phlegmons, carbuncles, furuncles, etc.

The advantages claimed by Bier and Klapp for this method of treatment are: (1) It is painless; (2) the pain due to inflammation is relieved very quickly; (3) no incisions, or at most very small incisions are necessary; (4) the abscesses heal in one-third to one-half the ordinary time; (5) there is no scar formation; (6) the method is simple.

Influenced by the results that I had witnessed of the successful treatment of inflammations by hyperemia alone, and by the accumulating mass of evidence, that has appeared since the publications of Bier and Klapp, which seems to confirm their observations, I applied the method to the treatment of acne, a condition in which these methods have not, so far as I am aware, been suggested. Eight cases have thus far been treated, and the results in every case have been so good, compared with those obtained by the ordinary and well-recognized methods in the treatment of this condition, that I have deemed it advisable to publish my results, even though I realize that the number of cases thus far treated is still too few to warrant general conclusions being drawn. In many of these cases the acne had been treated for months, or even years, with discouraging results.

The method is very simple. An ordinary dry cup with rubber bulb attachment is used. The edge of the cup must be broad, and the diameter varies from three-quarters of an inch to one and one-half inches, depending upon the part of the face to which the cup is applied. The cup is applied to the affected area of the face for one hour every day, preferably in the evening. If the application is made twice a day, for an hour at a time, more rapid results will be obtained. The suction must be of the slightest character, so that the least pull will separate the cup from the skin. This point is emphasized for two reasons; first, because greater suction is not so efficient, and may even aggravate the condition; and secondly, because if more suction is employed, a disagreeable ring may form which takes a day or two to disappear. The cup must be removed every one or two minutes, and reapplied to permit of a new influx of blood. The applications are begun over that area of the face in which the acne pustules are most numerous, and are repeated daily over the same area until the pustules have disappeared. The cup is then shifted to another part of the face, and a similar course is pursued. This is repeated until the entire face has been treated. It takes from two to five applications over each area, until a satisfactory result is obtained. It is needless to say that if two cups are used at the same time the duration of healing will be reduced one-half.

As far as I can determine, this method does not prevent the appearance of new pustules, although it has seemed that they relapse decidedly less frequently than before treatment was begun. As soon as a fresh pustule has appeared the cup must be reapplied, until it disappears. No other method of treatment was used in any of the eight cases.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, January 13, 1906.

THE DIFFERENTIATION OF THE STREPTOCOCCI.

THOUGH it was long believed that all streptococci were varieties of one and the same species, the idea has been gradually gaining ground that specific differences exist between the individual types which are real rather than apparent. No convincing evidence has been adduced, however, by means of which this perplexing question may be definitely decided. This uncertainty with regard to the relationship of the streptococci to each other is in marked contrast to the pathogenic importance of the group, which assumes an essential and considerable part in the course of many acute and chronic diseases. It has been sought to combat the effects of this organism by the use of an antitoxic serum, but the element of uncertainty which attends the present indiscriminate employment of the latter is certainly not in favor of any conception of a "unity" of the streptococci.

The characters of this type of microorganism which have been most frequently studied are their morphology, their mode of growth in various culture media, their exhibition of virulence in experimental animals, and, finally, their agglutinative and hemolytic properties. In a recent contribution to this subject, H. M. Gordon (*Lancet,* November 11, 1905), directs attention to the fact that the evidence obtained by comparing streptococci with reference to these points has not been made sufficiently convincing to lead bacteriologists to abandon their position of reserve, and the question naturally arises whether the criteria just referred to are the best by which the various members of this group of bacteria may be studied. Dr. Gordon believes that there are other inherent properties of streptococci in addition to those mentioned, by means of which the individual types may be discerned and identified. He has studied this matter very carefully for a number of years, and has subjected his theories to extensive tests. In an investigation of this kind the first matter to be determined was the nature of the cultural characters in regard to which streptococci exhibit the sharpest differences among themselves. As a result of the observations, a series of tests were found available for the purpose, the majority of which depended on the ability of the streptococci to manufacture acid when cultivated aërobically in slightly alkaline broths. These were kept for three days at a temperature of 37° C., and contained one per cent. of saccharose, lactose, or any one of a number of compounds belonging to the carbohydrate or glucoside series. The tests were applied to a large number of specimens of streptococci. Those obtained from normal human saliva all had two characters in common: they produced an acid reaction in broth containing saccharose, but failed to do so in that containing mannite. Then, again, those varieties most frequently found in feces all gave a positive reaction with broth containing salicin. It is evident that the existence of these and other similar reactions, if constant, will afford a means by which particular material from either the mouth or the intestines may be identified, as the types of streptococci noted were the most abundant organisms present. Dr. Gordon also obtained these characteristic streptococci of saliva from the air of inhabited rooms and those similarly characteristic of feces from air which had been contaminated by material from the shoes which was probably dragged in from the street.

When these tests were applied to streptococci from the body in disease, it was found that a considerable diversity existed, for example, among those obtained from cases of sepsis. In five cases of malignant endocarditis, organisms were found which were identical, as regards their reaction, with those streptococci found most frequently and extensively in human saliva. The stability of these reactions is shown by the fact that the streptococci responded to the tests in the same manner after being cultivated for periods of time up to two weeks, as when they were originally isolated. The tests here referred to were applied by Dr. Gordon in a careful study of the bacteriology of milk, water, saliva, excrementitious matters, and various morbid materials, and the results obtained constitute, in his opinion, a definite basis upon which the classification of the streptococci may be undertaken. Aside from this, the knowledge gained will also serve a good purpose in connection with the subject of serum therapy. As already stated, antistreptococcic serum is now used quite indiscriminately, and its employment is based on the supposition that streptococci are incapable of differentiation. No efforts are made, as a general rule, to secure a serum which shall be related to any particular strain of these organisms, for the very good reason, perhaps, that the older laboratory methods were insufficient to permit of any discrimination between them. It is to be hoped that the impetus given by this investigation may extend to further attempts at solving the practical questions which are involved in this combat against septic infection and its consequences, a solution which is most anxiously awaited by the medical profession.

CALCAREOUS DEGENERATION.

MANY theories have been advanced to account for this degenerative process, and yet only comparatively few facts are at hand upon which these may be actually based. Calcification is known to occur in divers tissues and the chemical nature of the salts present has been minutely described, but here further study has ended. Regarding the existence of pathological calcification there are abundant data, but as to the actual process, little is known. The older writings contain numerous references to the condition, and an excess of lime salts in the blood was commonly accepted as an explanation of its origin, while dead or dying tissues were regarded as a nucleus around which the carbonate or the phosphate of lime could crystallize. This view was later

superseded by a theory which was based on experimental studies dealing particularly with calcareous degeneration of the kidneys. Litten, who first broached the idea, had many adherents and as many opponents. According to this belief, an injury to the tubular epithelium of the kidneys is produced by the action of certain irritants as the latter are in process of excretion, and this results in a degeneration of the cell protoplasm. The degenerated cell protoplasm is supposed to have an affinity for, and fixes as an insoluble compound, the calcium salts brought to it by the lymph and the blood. A coagulation necrosis of the renal epithelium was, therefore, believed to be a necessary stage in the process. This view has been generally accepted; and yet it is noteworthy that no one has proved that outside of the body there is to be obtained the formation, even temporarily, of compounds of lime and any form of proteid. In order to determine with what organic substance present in degenerating tissues lime salts entered into combination, an extensive investigation was undetaken by Oskar Klotz, a report of which has lately appeared in the *Journal of Experimental Medicine* (Vol. VII, No. 6). It was undertaken to produce experimentally calcification of the kidney and other tissues, and to study the successive changes which took place in these. In all the experimental work on animals and in the analysis of degenerating human tissues, the interesting fact constantly presented itself that calcareous degeneration is preceded or accompanied by deposits of a soapy material. This soap exists in chronically inflamed tissues in advance of the deposit of lime, or it appears in the peripheral zone of the calcareous infiltration. Calcium salts are immediately attracted to it from the body fluids, and in recently calcified tissues there is present an actual calcium soap. Klotz was able to induce deposits of calcareous salts in the lower animals within celloidin capsules containing soaps and fats inserted in the peritoneal cavity, also in the kidney and in connection with fat necrosis.

We cannot review here the very voluminous details of these investigations, but attention may be called to some of the writer's conclusions. Bone formation and pathological calcareous infiltration were found to be wholly distinct processes; in the former there is no evidence of associated fatty change, in the latter there is an antecedent fatty change in the affected areas, and the cells involved present constant evidences of degeneration. The view that would seem, according to Klotz, to account best for the changes observed in the latter case is that, with lowered vitality, the cells are unable to utilize the products brought to them by the blood, so that the normal decomposition associated with their metabolism fails to take place. They interact, therefore, among themselves, with the result that insoluble compounds replace those of a soluble character. Klotz has also demonstrated the presence of soaps in areas which are undergoing calcareous infiltration, and this often in such quantities that they can be isolated and estimated by gross chemical methods.

While these are the facts, certain of the details of this reaction demand elucidation, for the existence of sodium or potassium soaps in the degenerated cells can be explained only by assuming that they are present in the circulating lymph and undergo absorption. But if they are diffusible, there must be some reason for their being stored up in some particular tissues. The indications are that in cells undergoing degeneration, with degeneration of the cytoplasm certain albuminous molecules unite with the soaps present to form a relatively insoluble soap-albuminate. These albuminates can actually be formed with calcium soaps in the test tube.

The fact that in older areas of calcification, soaps are entirely or largely wanting, and the reactions are those principally of calcium phosphate, would seem to indicate that the final stage in the process is an interaction between the calcium soap-albuminate and substances containing phosphoric and carbonic acids, which, as is well known, are present in considerable amounts in the lymph and blood. The experimental studies here noted are of great interest and will tend to a revision of the previously accepted ideas of calcareous degeneration. It will be interesting to note how this new knowledge will affect, if it affects it at all, the treatment of this widespread condition.

THE PROLIFERATION OF TYPHOID BACILLI IN THE GALL-BLADDER.

There are a number of factors connected with the etiology of typhoid fever which have been explained on hypothetical grounds rather than through the medium of exact bacteriological investigations and unprejudiced observations. These include the recurrence of epidemics of the disease in certain houses or localities, sometimes after long intervals, and the occurrence of sporadic cases in the midst of a completely healthy environment. These phenomena have been ascribed to a peculiar tenacity of the typhoid bacilli, by which they were able to lead a saprophytic existence for prolonged periods in the water or the earth, only to be a source of a new infection under favorable circumstances. In the sporadic cases it was simply assumed that the source and path of the infection had escaped the attention. The error and falsity of these views have been disclosed to a large extent by the efforts of Koch and his followers; the significance of earth and water infection has been relegated to its proper sphere, and the principal factor in the spread of the disease has been proved to be a contact infection, or in other words the direct or indirect transmission of the pathogenic organism from a sick to a well person. The appearance of sporadic typhoid cases after prolonged intervals has also been accounted for by the discovery that persons who have apparently recovered from the disease may continue to pass the germs with their stools for months afterwards and thus innocently serve as a source of infection for others.

The problem which remained was in reference to the carriers of the infection themselves. The continual or occasional elimination of the specific germs with the stools presupposes a constant regeneration of the infectious organism of the intestine. This state of affairs can be accounted for only by assuming that the typhoid bacilli remain within the lumen of the intestinal canal, and while the mucous lining of the latter remains intact, continue to proliferate in this locality as saprophytic organisms and like the colon bacillus under similar circumstances, constitute a member of the normal intestinal flora.

Another interesting explanation of this condition is advanced by R. Doerr (*Centralblatt für Bakteri-*

ologie, October 10, 1905), who bases his theory on the supposition that the gall-bladder may act as a reservoir into which the typhoid bacilli may enter and continue to proliferate, only to be expelled into the gut with the bile by the contractions of this viscus. It is a matter of common knowledge that the gall-bladder constitutes a favorite hiding place for the typhoid germ, which may induce there an inflammatory reaction of greater or less extent. In a case of suppurative cholecystitis complicated by cholelithiasis, personally observed by Doerr, enormous numbers of Eberth's bacilli in pure culture were obtained from the purulent contents as well as from the concretions. The condition in the gall-bladder had developed about six months after a mild attack of typhoid fever, which was not diagnosed at the time, and it could be readily demonstrated that with each attack of biliary colic a large number of the typhoid organisms were expelled into the intestinal canal and passed with the stools. Desiring to ascertain the manner in which infection of the gall-bladder took place, Doerr made a series of inoculation experiments in rabbits and found that the germs could enter this viscus only through the medium of the circulation, and that even here intravenous injections alone were successful in transmitting the infection. It was found, moreover, that the process was kept up by a proliferation of the organisms *in situ* rather than by a reinfection from without. Attempts were also made to devise a means for getting rid of the germs in the gall-bladder, but all the usual antiseptic remedies employed were ineffectual in attaining this end.

The observations made by these investigators are of considerable importance, for they explain a number of hitherto doubtful phases of typhoid infection. So long as we can apparently do nothing to influence this localized process in the gall-bladder, all that remains is a thorough examination and disinfection of the stools of the convalescing typhoid fever patients for considerable periods, and as long as the germ can be demonstrated, these patients should be regarded as foci of danger, although seemingly well.

THE CONSENT NECESSARY FOR SURGICAL OPERATIONS.

It has been adopted as a general rule that a formal consent must be obtained by the surgeon from either the patient or one of the immediate family, before any operative procedures are undertaken. Instances are likely to occur, however, in which a surgeon, from lack of foresight or through a zealous desire to act quickly in order to save life, may be led to forego this precaution and as a result may later on find himself involved in legal difficulties. This is, perhaps more apt to occur when the operation has been unsuccessful or has ended fatally, and the friends or relatives see an opportunity to make capital out of the failure of the physician to comply with the letter of the law. In view of the fact that the law has apparently been tested in numerous instances, we might be led to expect that a more definite knowledge should exist of the conditions which make a surgical operation lawful under the circumstances referred to. According to J. F. Shields, however, (*Annals of Surgery*, November, 1905), only four decisions bearing on this subject have, up to the present time, been rendered by courts of the last resort within English or American jurisdiction.

In order to secure a clear analysis of this subject, it will prove a material aid to divide the requirements for a surgical operation into two classes: First, those in which a surgical operation is advisable, but an immediate operation is not imperative to save or to prolong life; and secondly, those in which an immediate operation is necessary as the only course of treatment known which will save or prolong life. Consent in either case may be express or implied, and in all the cases referred to, the law assumes implied consent when the patient places himself in the hands of a physician or surgeon and submits to an operation. This is the law as it appears to be, but as Mr. Shields suggests, it is advisable for the surgeon to obtain full and clear consent in all cases whenever possible, in order to save himself annoyance and expensive litigation. This presupposes, of course, that the patient is an adult and in good mental health. In the case of lunatics, the surgeon should first have the person legally declared such, if time permits, and then obtain the consent of those in legal charge. If the urgency of the case does not permit such delay, the consent of those directly in control of the lunatic and also the consent of the latter, if possible, should be secured. As regards minor children, the consent of both parent and child should be had, if possible. In the case of a child under the age of fourteen, the parents' consent is especially necessary to protect the surgeon against litigation. Over the age of fourteen, the consent of the child alone would appear to be sufficient. Finally, the fact holds that in all cases of sudden and critical emergency the law will justify the surgeon's act, on the assumption that consent to the operation implies consent to measures for the relief of any condition arising from it and demanding immediate action.

The Physician's Sunday.

To the mass of the public the personal life of the physician is a little-thought-of and usually not-at-all-considered element. It is but natural that when sickness or physical disaster enters a household its members should regard the matter only from their own standpoint and easily overlook the fact that the medical attendant on whose judgment and skill they are relying deserves and requires time for rest and recreation. Sundays and holidays usually bring but little change into the daily program of the practitioner, who is obliged early in his career to accustom himself to a routine of exacting work with but few interruptions for relaxation. Sunday is on the European continent regarded more as an opportunity for recreation and less as an occasion for the expression of devotion than is the case in this country, and the German physicians are beginning to chafe under the restrictions to the enjoyment of family life imposed by the conditions under which medical practice is at present conducted. At a recent meeting of the Medical Society of Frankfurt a. M., Dr. Arnold Eiermann presented for ratification by the members a plan intended to secure for the city's medical men the desired opportunity of enjoying a weekly excursion with their families unclouded by the ordinarily ever-present fear of some emergency arising in their absence. The proposal was made to divide the city into seventeen districts, corresponding to the police divisions, and that the physicians of each section, one at a time, should take turns in being on duty in their districts on Sundays and holidays. The others would be at liberty to leave the city. The name of the physician in charge

would always be obtainable at the police station, and the lists for the entire city would be printed in all the newspapers. Of the specialists, only one in each branch would be required to be on call, except in surgery and gynecology, which would need two available representatives. The physicians on duty would be obligated promptly to mail to the attending physician a printed form filled in so as briefly to furnish the most important features of any calls made on strange patients. The outline of this plan was published in the *Münchener medizinische Wochenschrift*, November 28, 1905, and it is stated that it was accepted by a unanimous vote of the society. That the details of such an arrangement have not been found insurmountable is shown by the fact that a despatch to *The Sun*, dated January 6, announces the inauguration of the plan on January 14, so that after that date the life of the Frankfort physician will be much less arduous than before. While the project in the form proposed would probably not be feasible in this country, the advantages it offers are self-evident and it would be very desirable if some analogous scheme of mutual help could be universally introduced.

The California Board of Medical Examiners.

One of the periodical outbursts against the California State Board of Medical Examiners has recently taken place at Los Angeles. A physician who lost two sons in a battle with the board threatens suit on the ground that his boys were "plucked" through malice against the College of Physicians and Surgeons, from which they were graduated in June. It is charged that the president of the board shows a dislike for the name of this institution, and has expressed a determination to prevent any graduate of the College of Physicians and Surgeons of either Los Angeles or San Francisco from receiving a license to practise, though he had to sacrifice other candidates to do so. Another physician charges unfairness, and calls the president a trickster, supporting the charge with several specifications, but this physician also has felt a wound, for he himself failed to pass the examination in bacteriology before the board. Several of the most prominent members of the Los Angeles profession have come to the rescue of the president of the board in just as emphatic language as that used by the disgruntled ones. It must be admitted that the standard set by the California board is a high one, but it should be maintained, for the State is a Mecca of the quacks of Christendom. A review of the questions submitted at any examination shows that they are selected in every branch with remarkable skill, both with a view to fairness and as a test of the knowledge of the applicant. Unfortunately, the president of the board is said to have made a custom of submitting two questions at the close of each test which are particularly obnoxious to even the best bacteriologists, one requiring the diagnosis of a culture tube, the other the naming of a stained specimen of bacteria, without any information as to the preparation of either, each question counting ten per cent. in the final average. Possibly he has been indiscreet in some of his remarks, but the evidence against him comes from unfortunate candidates, many of whom prove themselves incapable of answering the simplest questions in almost any branch.

Harvey Society Lecture.—The fifth lecture in the Harvey Society course will be delivered at the New York Academy of Medicine on Saturday, January 20, at 8.30 P.M., by Dr. W. H. Park. The subject of the lecture will be, "A Critical Study of Serum Therapy." The lectures are free to the profession, and all interested are invited to attend.

News of the Week.

Health Statistics of Illinois.—According to the report of the Illinois State Board of Health, 65,000 deaths occurred in the State of Illinois in 1905. In the same period there were approximately 150,000 births, making a net increase of 85,000 in the State's population. Births of males exceeded females by fully 6,000. The statistics show that consumption continues to cause more deaths than any other disease, with pneumonia and heart disease second and third. The annual report shows that there are more than ten thousand physicians licensed to practise in the State, and the Board examined and licensed 850 physicians in 1905. Under the act of the last General Assembly providing that the State Board of Health shall license all embalmers, 1,700 embalmers have been examined and received certificates. The inspection and supervision of lodging houses in Chicago have had the effect of abolishing all basement lodgings, of doing away with all double-deck and treble deck bunks, and of securing far better sanitary conditions.

To Help the Blind.—The New York State Association for Promoting the Interests of the Blind, is an organization which developed from a movement begun three years ago for the purpose of collecting tickets for musical and dramatic performances and distributing them to the blind who could not otherwise afford them. The originators of this plan came personally in contact with the blind and were impressed with the fact that, either for lack of training or opportunity for work, many of them who were able bodied, were forced to be dependent for their support, partially or entirely, on the State, on the City, or on private philanthropy. Therefore a society similar to that in Massachusetts, was created, and in addition to distributing tickets the organization sends visitors to the blind in their homes, where they give practical suggestions to help those willing and able to work, and bring cheer and courage wherever possible. The Employment Bureau, using the information gathered by the visitors, will try to find remunerative occupations for some blind people in their homes, for others in handicraft shops for the blind—in factories for the seeing, and for some in mercantile and professional pursuits. Contributions may be sent to Miss Winifred Holt, 44 East Seventy-Eighth street, New York. The association will hold its first public meeting in this city, on March 29, 1906. Mr. Clemens (Mark Twain) will preside and the Hon. Joseph H. Choate and Miss Helen Keller will speak.

Autopsy Dispute.—The occurrence of misunderstandings in regard to autopsies on hospital patients gives rise to frequent disputes between hospital authorities and the friends of patients. The District Attorney has been called upon to investigate a recent instance of this sort in which it is alleged that a post-mortem examination was made at an uptown hospital without due permission from the relatives of the deceased. The fact that the abdominal viscera were retained and excelsior substituted for them is apparently considered the chief grievance.

Painless Death for Incurables.—The advocates of euthanasia have received a distinguished recruit in the person of Dr. Charles Elliot Norton of Cambridge, well known as a man of letters. In an open letter addressed to Miss Anne S. Hall of Cincinnati, who at a recent meeting of the American Humane Association presented a resolution

calling for approval of the practice of ending the life of the hopelessly insane, incurably diseased, or the victims of accidents, Dr. Norton speaks in very strong terms in favor of such a course. Prof. Norton, it should be remembered, is not a doctor of medicine, his doctorates—Litt.D., LL.D., and D.C.L.—being honorary merely, and adding no weight to the expression of these murderous ideas.

Chicago Schools to Be under Sanitary Rules.—Children affected with tuberculosis henceforth will be put in separate buildings. The Public School Board of Chicago will cooperate with the Health Department in fighting the disease. The plan contemplates the organization of a large corps of trained nurses to visit the homes of school children from which illness has been reported; the examination of children before permitting them to return to school from homes in which there has been contagion; to secure enforcement of the law calling for the placarding of the houses in which there is contagion; to give special attention to the teaching of sanitation and health laws in the schools of the congested districts, and to bring to the notice of the proper charitable organizations all families found to be in need of help.

Striking Physicians.—According to the London *Express* the entire staff of medical men attached to the Exeter Dispensary have decided to strike. Insults, they declare have been heaped on them and "the profession of medicine degraded by the base calumnies of the committee." The trouble has arisen from a proposal by the committee to appoint a paid medical officer. The incident recalls the story told of a similar attempt in Italy a score of years ago which was very neatly squelched by the government. In 1886 the medical staff of the hospitals of Rome decided to strike on a certain day. When the day arrived each physician received from the Ministry of War a commission in the army, with orders to report for service to general officers who had simultaneously been appointed to take charge of the various hospitals. In these circumstances a strike would have been "mutiny." There was no mutiny among the new members of the Italian army's medical staff.

The Yerkes Hospital.—From statements made by Mrs. C. T. Yerkes, it appears not unlikely that an effort will be made to begin the erection of the hospital provided for in her husband's will at a much earlier date than was the testator's intention. The will directs that the work should not commence until after the death of Mrs Yerkes, as she has a life interest in the residuary estate, but Mrs. Yerkes has expressed the desire to have the hospital built under her own supervision.

The Home Treatment of Consumptives.—Attention has repeatedly been called in the columns of the MEDICAL RECORD to the undesirability of sending impecunious consumptives long distances from home for treatment. The Committee on the Prevention of Tuberculosis of the Charity Organization Society has sent to a very large number of physicians a letter emphasizing this fact and discouraging the practice of recommending "the country" or the "West" to the poor consumptive. The letter of the Committee states that experience has taught us that, difficult as it may be for a poor man to recover from tuberculosis in this city, he is better off here among his friends and relatives, where there are more adequate hospital and dispensary facilities, than he is far from home, where he is thrown entirely upon his own resources and where the great number of consumptives willing to work at the lowest wages make the finding of employment, especially of suitable employment, almost impossible. Favorable results from climate can hardly be looked for unless at least $10 per week can be spent for board and lodging. The stranger, who has spent a large part of his savings on railroad fare, soon finds himself without work, living in the poorest rooms, eating the scantiest and cheapest food. The practice of advising the removal to other climates thus defeats its own aims and casts upon the charity of other communities a burden which they should not and cannot sustain. The cooperation of the medical profession is, therefore, invited to prevent persons suffering from tuberculosis from being sent to other States unless they are physically able to work and have secured in advance a definite assurance of the opportunity to perform work of a proper character at wages sufficient for their suitable support or they have at their disposal at least $250 in addition to railroad fare.

Steamboat Whistling.—In response to the strenuous objections made by Mrs. Rice and other residents along the city's various waterfronts, the National Board of Steam Navigation, comprising the owners or managers of all the ferryboats and nearly all the tugboats in the harbor, has passed a resolution directing its members to instruct the masters and pilots of their steam craft to blow their whistles only when absolutely necessary to conform with the law.

"Archives of Pediatrics."—With the close of the year 1905 Dr. Walter Lester Carr, who for five years has been editor of the *Archives of Pediatrics*, retires from official connection with that journal. Dr. Carr's successful editorial management will render the work of his successor no easy matter, but we doubt not that under the guidance of the new editor, Dr. L. E. La Fetra, the *Archives* will maintain its established reputation as the leader among the journals devoted to the diseases of children.

Cook County Hospital Growth.—The warden of this institution, Mr. Chas. J. Happel, in his annual report, shows that the institution had more than 100 patients each day in excess of the daily average of last year. The daily average of patients in the County Hospital is 917; the daily average of patients in the detention hospital, 17, making the daily average for both 934 patients. Deaths in the County Hospital were 1,776; deaths in the Detention Hospital, 12; total, 1,786 for the year.

Vapor Anesthesia.—A conference of the interne anesthetists of the Brooklyn Hospitals was invited to assemble at the Long Island College Hospital on December 19, by the anesthetists of that institution. Dr. Bull, the house anesthetist introduced Dr. J. T. Gwathmey, who presented his new vapor inhaler. The interest of the demonstration was increased by the offer of Dr. A. F. Erdmann to submit to a narcosis by means of the inhaler. This was done, and the "patient" afterwards testified to the entire absence of unpleasant sensations. The meeting in January is to be held in the Bushwick Hospital, under the direction of Dr. Woolsey, the consulting anesthetist.

Annual Report of Dunning (Ill.) Institutions.—The superintendent of these institutions, Dr. V. H. Podstata, in his annual report shows a decided increase in the insane population over the previous year. Notwithstanding the fact that 57 patients in the year have been transferred to

various State institutions, the total population of insane patients increased over 200. At present there are at the Dunning Insane Asylum 1,840 patients. There are now about 80 more patients at the consumptive hospital than there were last year, the population now being 170 patients.

San Bernardino County (Cal.) Medical Society.—The annual session of this society was held at Arrowhead Hot Springs on December 13, 1905. The following officers were elected for the ensuing year: *President*, Dr. Thos. M. Blythe of Redlands; *Vice-Presidents*, Drs. Jos. A. Champion of Colton and Chas. E. Ide of Redlands; *Secretary*, Dr. D. C. Strong of San Bernardino; *Treasurer*, Dr. John H. Evans of Highlands.

College of Physicians of Philadelphia.—At a stated meeting held January 3, the following officers were elected for the ensuing year: *President*, Dr. Arthur V. Meigs; *Vice-President*, Dr. James Tyson; *Treasurer*, Dr. Richard H. Harte; *Secretary*, Dr. Thomas R. Neilson; *Honorary Librarian*, Dr. Frederick P. Henry.

Diphtheria Spread by Pencils.—An investigation by the Kansas State Board of Health disclosed that an epidemic of diphtheria in a small town was caused by public ownership of lead pencils. The school board buys pencils for the pupils, and these are gathered up each night and distributed in the morning. One child contracted diphtheria and in a few days the disease was communicated to fifty pupils by means of the pencils. The State board ordered the pencils destroyed and the system abolished.

Tuberculosis Exhibition in Boston.—The tuberculosis exhibition, of which the New York collection of material formed the nucleus, was held in Boston, December 29 to January 7, and excited much popular interest. It will be transferred to Philadelphia and will be opened there on January 22.

Health Conditions in Chicago.—The death rate of Chicago for 1905 will be less than 14 per 1,000 of population, a considerable gain over the figures of previous years. In 1873 the average age of those dying was fifteen years, but now it is over thirty-two years.

New York Neurological Society.—At the annual meeting, held on January 2, 1906, the following officers were elected for the ensuing year: *President*, Dr. Joseph Fraenkel; *Vice-Presidents*, Drs. Adolf Meyer and J. Ramsay Hunt; *Recording Secretary*, Dr. Edwin G. Zabriskie; *Corresponding Secretary*, Dr. F. K. Hallock; *Treasurer*, Dr. G. M. Hammond; *Councillors*, Drs. M. Allen Starr, Charles L. Dana, Joseph Collins, J. Arthur Booth, and William M. Leszynsky.

Western Surgical and Gynecological Association.—At the fifteenth annual meeting of this society, held in Kansas City, Mo., December 28 and 29, 1905, under the presidency of Dr. H. D. Niles of Salt Lake City, the following officers were elected: *President*, Dr. Malcolm L. Harris of Chicago; *Vice-Presidents*, Drs. A. L. Wright of Carroll, Iowa, and C. Lester Hall of Kansas City, Mo.; *Secretary and Treasurer*, Dr. Arthur T. Mann of Minneapolis. Salt Lake City was selected as the place for holding the next annual meeting, in December, 1906.

The Canadian Method of Dealing with Dangerous "Christian Healers."—A Dowieite leader at Toronto and Dowie's representative in Canada was sentenced, on January 8, by Judge McCrimmon, senior judge of the county of Ontario, to six months with hard labor in the Central Prison, Toronto, for "aiding, counseling and abetting one Marshall Harmon, of Victoria Corners, township of Brock, in neglect in securing medical assistance during his wife's last illness."

South Texas District Medical Association.—At the close of a two days' session at Beaumont, Texas, the following officers were elected for this association: *President*, Dr. D. S. Wier of Beaumont; *Vice-Presidents*, Drs. P. G. Swearingen of Center, and Jordan of Liberty; *Secretary and Treasurer*, Dr. A. A. Nelson of Nocogdoches. Houston was selected as the place for the next meeting, which will be held in June, 1906.

North Texas Medical Society.—At the fiftieth annual convention of this society in Dallas, which ended December 13, the following officers were elected: *President*, Dr. Joe Becton, Greenville; *Vice-President*, Dr. J. F. Corry, Rockwall; *Secretary*, Dr. H. L. Moore, Van Alstyne; *Treasurer*, Dr. C. A. Gray, Bonham. The next semi-annual meeting will be held at Denison, in June, 1906.

Dr. William Osler is now in Baltimore, and, according to an unconfirmed report in the *New York Times*, wishes to return there to live. The report says that it is the belief of many medical men of Baltimore that he will resign the Regius Professorship of Medicine at Oxford and return to his old chair at the Johns Hopkins.

Yellow Fever is now said by the sanitary authorities of Havana to be extinct in that city.

Obituary Notes.—Dr. W. E. Hemphill of Asheville, N. C., died of appendicitis on December 24, after an operation. Dr. Hemphill was thirty-five years old and had been in practice since 1896. He was coroner of Buncombe County.

Dr. J. M. Ely of New Palestine, Indiana, died on December 14, at the age of eighty-four years. He was born in Nashville, Tenn., and had practised medicine for over sixty years.

Dr. John C. Campbell of Nebraska City, Neb., died on December 12, at Asheville, N. C. He was born near Lexington, Ky., December 22, 1814, and lived there eighteen years. He attended Miami University, coming to Burlington, Iowa, in 1836. In 1840 he graduated in medicine and practised in several towns in Iowa, finally going to Nebraska City in 1854.

Dr. C. L. Stewart of Detroit, Mich., died of appendicitis on December 25. Dr. Stewart was a graduate of the Detroit College of Medicine, thirty-eight years old, and for the past four years had been milk inspector for the Board of Health.

Dr. James L. Harriman of Hudson, Mass., one of the best known physicians of Middlesex county, died on December 29, at the age of seventy-two years. He was graduated from Bowdoin College in 1857, and served through the Civil War as surgeon of the 13th Massachusetts regiment.

Dr. Putnam Fulkerson of Lexington, Mo., died on December 16, after a short illness. He was born at Abingdon, Va., and was in his eightieth year. He had lived in Missouri since 1845 and for fifty-nine years had practised medicine.

Dr. Francis Rowan Webb of Chicago, Ill., is dead of pneumonia. Dr. Webb was born in Chicago in 1851. He was educated in the Chicago schools and afterwards at Rush Medical College. He had a general practice until a few years ago, when he gave it up to devote himself to pathology.

Dr. George Kassen of Cincinnati died on December 11. He was a native of Germany and received his medical education at Wurzburg, and at the Miami Medical College. He had a

large practice among the German residents of Cincinnati.

Dr. James W. Holland of Westfield, Mass., died on December 30 of nephritis, on his thirty-eighth birthday. He was graduated from the medical department of the University of Pennsylvania in 1894, and immediately returned to his home town and began the practice of medicine. He was elected as a member of the Board of Health and also appointed town physician. In July, 1900, he was appointed surgeon of the United States Army and assigned to duty in the Philippines. After two years he returned to Westfield and was appointed associate medical examiner for the western district of Hampden County.

Dr. Charles E. Wentz died at New Providence, Lancaster County, Pa., on January 3, at the age of twenty-eight years. He was a son of Dr. Wm. Wentz and a brother of Dr. Frank Wentz. He was a graduate of the Medico-Chirurgical College of Philadelphia.

Dr. Henry C. Bowen of Cleveland, O., died on December 13, in his eighty-seventh year. Dr. Bowen came to Cleveland in 1841 from Fayetteville, N. C., where he was born, and in 1853 was graduated from the Cleveland Homeopathic Medical College. He continued practising until four years ago, when, because of failing health, he retired from active life.

Dr. Horace M. Nash of Worcester, Mass., died on December 24, at the age of sixty-one years after an illness of only a few hours. Dr. Nash had practised in Worcester five years, and previous to that he practised for twenty years in South Lancaster. He was born in Bath, Me., and in 1876 graduated from the University of Vermont. He began practising in Manchester, N. H.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL SUNDAY FUND AND ANTIVIVISECTIONISTS—TREATMENT OF TUBERCOLOSIS WITH T. R.—SEAMEN'S HOSPITAL—GENERAL COUNCIL'S WARNING—MITCHELL BANKS LECTURE.

London, December 22, 1905.

There was a large attendance at the Mansion House on Monday when the Lord Mayor presided over the annual meeting of the Hospital Sunday Fund. It transpired during the proceedings that the unusually large assembly was the result of a canvas made by the society of antivivisectionists which owns as leader Mr. Stephen Coleridge. The feeling elicited by the exposure of his pettifogging trickery was not exactly unanimous, but the condemnation after he had vainly moved an amendment and asserted that large sums were diverted from the sick poor to the schools extended far beyond the Mansion House and is evidently enlightening the public.

Indeed, in a letter to the *Times* one of the faddists declares that "hundreds" of those who voted at the meeting were not constituents of the fund. This seems an apt illustration of the methods of Mr. Coleridge and his clique. Surely an active canvass to pack the meeting with the antis is a sufficient proof of the absurdity of the plea. It was shown at the meeting circulars were sent to the clergy of London asking them to entrust their tickets of admission to Mr. Coleridge's Society. A considerable number of clerics were present at the meeting, many, no doubt, attracted by the circulars and canvass. But in spite of all, Mr. Coleridge's proposal was rejected by an almost unanimous vote, but not until one speaker had told him to his face that his talk about the sick poor was simply cant, his real object being merely to push his agitation, in support of which he was ready to sacrifice the interests of the patients about whom he professed such concern.

Archdeacon Wilberforce naturally put in another appearance as an antivivo. He subscribed, he declared, to every word said by Mr. Coleridge, and then held out a threat which must have shocked many of those present. He actually said he held at present a considerable sum from a hospital Sunday collection and if Mr. Colridge's amendment was not carried he would not apply it to the fund. By what casuistry he justifies himself in not handing over the money to the fund on behalf of which it was collected is not for honest men to say.

He ought not to have retained it so long, and unless it is forthwith sent to the fund some one should undertake to show him that his conduct looks like that of a fraudulent trustee.

The treatment of tuberculosis by means of the new tuberculin has been fully discussed of late—two evenings at the Medico-Chi. being largely devoted to it and producing some important papers and details of research. Dr. A. E. Wright discussed the general principles of bacterial vaccines. He classed infections as local and systemic. In the former immunization was not present and the protective power of the blood was below normal. In the latter immunization occurred and the protective power fluctuated. In localized infection this protective power should be raised and the anti-bacterial lymph brought into contact with the organisms in the lesion. In the systemic infection, as in pyrexial tuberculosis, there is constantly recurring autoinfection, and the object is to arrest this if possible.

A paper by Drs. David Lawson and Struthers Stewart contained tables showing comparisons between the opsonic index of the blood of healthy persons and those with pulmonary tuberculosis and some who had recovered. They attributed value to these differences, both in respect to the diagnosis and treatment, and thought tuberculin increased the proportion of cures and tended to prevent relapses.

Dr. Bulloch read a paper giving the results of his experience with tuberculin R. Of eleven severe localized cases five were apparently cured, four improved much, in one the treatment could not be tolerated, and in one death took place in spite of it.

Mr. John G. Pardoe read a paper on Tuberculin R. in urinary cases—chiefly those of primary tubercle of the bladder or those in which the condition of that viscus is the main feature and, as far as can be judged, the primary infection. He thought injections of all kinds into the bladder injurious and the less the organ is subjected to instrumentation the better. When the cystoscope is required the greatest care is needed to prevent septic infections, for "sepis is to a tuberculous bladder as fire to tow." As Harry Fenwick has shown, T. R. is dangerous where both ureters are affected, therefore the cystoscope must be used before commencing the treatmnt. Total suppression by blocking of the ureters has occurred from neglect of this warning. T. R. must therefore never be employed unless there are, on at least one side, both a clear orifice and a free flow. Of twenty-one cases treated Mr. Pardoe reported five seemed to be cured, but remembering the tendency to relapse he contented himself to call them apparent cures and proposed to give their later histories in a future paper. Tuberculosis of the urinary system has such long periods of latentcy that a year more's respite cannot be called a cure. Mr. Pardoe said his experience of other treatment has been so disappointing that he did not think it optimistic to state that the results with injections of T. R. are at least as good as those by any other method. Before he used it he had little hope of getting any improvement. Now he thinks there is hope of cure in some cases and of great improvement in more.

Sir R. D. Powell (President), compared the positive and negative phases produced by active ulceration with the effects of injections of serum. In many cases discharged from sanatoriums the opsonic index had been low. He thought this index might indicate the amount of exercise a patient should take, for if it were high the flushing of the lesion by exercise would be good; if low, harm would probably be done. He anticipated a time when a clinical index would be discovered, for it is impracticable to make opsonic observations in the general run of cases. I must confess to some satisfaction at this admission by so great an authority as Sir Douglas, for it seems to me pretty clear that the bacteriological skill required to estimate opsonic reactions, to say nothing of the time consumed, precludes the general employment of this method, and after all there seems at present something hypothetical about opsonins. Not that I would speak disrespectfully of them any more than I would of the equator. But I have a sort of notion—prejudice if you like—that careful clinical observation of the effects of treatment must continue to furnish important information, if it cannot be as exactly measured as some of the laboratory researches.

But to return to the discussion—Dr. G. W. Ross found in one hundred cases in a consumption hospital the opsonic index was above normal in fifty-one per cent.; in eleven per cent. it was below normal. Of thirty advanced cases twenty-five showed a fluctuation in the index at different times. As a rule the index rose with the temperature, fell on confinement to bed, and rose on taking exercise. In

acute illness a low index was against its being tuberculous. He expected good results from the treatment.

Dr. Whitfield had had improvement in some skin cases —one of lupus was slightly better, two of scrofuloderma had done very well, as had two of erythema induratum.

Dr. Emery did not consider the index was always in proportion to the opsonins, but that the organisms varied in the facility with which they were taken up. He had seen cases improve, and in small doses the T. R. would not be injurious with a low index. He suggested the possibility of preparing an opsonic serum for use in rapid infections in which vaccines were inadmissible.

Dr. B. Harris advocated the use of very small doses. Better results were thereby obtained. In case of lupus of years' standing, by rest in bed, followed by T. R., the nodules rapidly cleared up.

Dr. Bulloch said some apparently unsuitable cases of phthisis had improved.

Dr. Lawson said sanatorium patients should not be discharged with a low index.

The Seaman's Hospital Society is taking another step in advance—proposing to establish a new school of clinical medicine—and several medical and surgical leaders have agreed to assist. Other hospitals will join, some have already done so. I am amused to see in a morning newspaper an account of this new departure, in which the reporter informs the readers that the new school will enable qualified men to learn clinical medicine at home, instead of having to go to the continent or to the United States to finish up their knowledge.

The notice of the General Medical Council concerning advertising, canvassing and such like has appeared in all the journals, and offenders will, in future, scarcely venture to plead ignorance of the views of the Council.

Mr. Edgcombe Venning, F.R.C.S., received a knighthood among those recommended by the outgoing ministry.

Mr. Reginald Harrison went to Liverpool, and delivered, on Monday the first Mitchell Banks lecture in the university, which he did so much to establish and which seeks thus to perpetuate his memory. Besides this lectureship, founded in memory of the great surgeon, a new outpatient department of the infirmary was built with the subscriptions which came in for the memorial as soon as it was proposed.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

PHOTOGRAPHS OF PROJECTILES—GASTRIC PERISTALSIS—HEMATOGENOUS LUPUS VULGARIS—SPONTANEOUS COMBUSTION—RETAINED TESTICLE—LUPUS CARCINOMA.

VIENNA, December 26, 1905.

THE next to the last meeting of the Association of Physicians was held in the lecture room of the First Surgical Clinic of Councillor von Eiselsberg in the Allgemeine Krankenhaus.

At von Eiselsberg's request the room had been completely renovated and newly equipped with modern appliances as compensation to Eiselsberg for not having responded to the call to the Berlin clinic. By means of the skiopticon numerous surgical pictures were demonstrated. An especially interesting series of photographs represented projectiles in motion and were made under the auspices of the Prussian Department of Education. The Prussian infantry projectile of the model of 1898 was photographed by the aid of electric apparatus with an exposure of one millionth of a second. At short distances terrible explosive effects are produced, which are made visible in series of photographs taken after the projectile has left the tissues. Numerous aspects of modern surgery were presented by the aid of *x*-ray pictures, and then von Eiselsberg demonstrated the new aseptic operating room which is probably the most complete product of modern skill in this direction.

Dr. Kaufmann has presented the results of interesting observations on gastric peristalsis. It has been generally accepted that the stomach is divided into a gastric and a pyloric portion by a circular constriction. Kaufmann instituted experiments in order to ascertain whether this division into two portions during peristalsis does really take place. He introduced a glass tube into the esophagus of a dog that had been narcotized with chloral and morphine, and inserted another into the pylorus. Water was then allowed to flow into the stomach. As long as the organ remained at rest the water flowed freely through the pylorus, but if the stomach was subjected to irritation, active waves were set up which occluded the pyloric antrum so that the outflow of the water filling the fundus was completely checked. In other words a second sphincter was formed in the stomach, dividing the cavity of the fundus from that of the pylorus. A model was demonstrated to illustrate the movements of the stomach during peristalsis. If one end of a flexible tube is held still and the other is twisted about its longitudinal axis both the ends will be approximated and two cavities will be separated from each other. How should the muscle fibers of the stomach be arranged in order to bring about such a rotation? They should run diagonally over the surface of the organ, and Kaufmann by the following experiment showed that they caused rotation and an approximation of the two extremities of the viscus. While the stomach was at rest he inserted into it long surgical needles to the ends of which straws were fastened; these were parallel to each other. On irritating the stomach the upper needles were twisted toward the head of the animal and the lower ones in the opposite direction until the angle between the two finally was almost ninety degrees, thus proving that the two portions of the stomach are shut off from each other by a constriction of this type.

Dr. Török of Budapest has described one of the rare cases of embolic hematogenous lupus vulgaris. The patient was a boy of two years who had had measles a year and a half before. A short time afterward the present eruption appeared and the number of cutaneous lesions increased rapidly so that within four months it had almost attained its present appearance. Since then new foci have appeared, but only in very limited numbers. A fungous gonitis has also developed on the left side. The foci, which are 157 in number, are mostly localized on the upper and lower extremities, though a few are seen on the face. The trunk and scalp are free from them, the surface of the infiltrated areas varies from the size of a bean to that of a twenty-five cent piece, and they occupy the superficial portions or the entire thickness of the epidermis; they are round, brownish or brighter red in color, soft in consistency, and in places are covered with fine scales. On the hands and feet they are either eroded or covered with wartlike proliferations of the epidermis. On admission these areas were covered with thick scabs. Such cases are observed very rarely, but the embolic nature of the disease is demonstrated in the present instance through the appearance of the foci in a relatively short time and their localization on the extremities and on the face, which are the situations of predilection for emboli. It appears that the embolic origin of tuberculosis of the skin when the matter is carefully investigated will be found to be more frequent than is usually believed. On another occasion, Török saw a child of eight months whose middle finger of the right hand, and right foot, exhibited a spina ventosa of tuberculous origin, while on the left labium majus there was a submucous infiltration the size of an almond and involving the entire thickness of the skin, surrounded by several apparently follicular suppurative foci. The mother of the child died of tuberculosis after its birth. A third case was that of a four year old boy who two years ago after measles developed on his neck an ulcerated area which is now occupied by a lupus patch the size of a silver dollar. The same patient also developed at the same time a periostitis of the index finger of the right hand, which still persists.

Dr. Karl Albecker has recently observed a curious case of burning which in all of its details suggests the instances of spontaneous combustion spoken of in the older textbooks, and proves that our understanding of the combustibility of the human body is very deficient. The body of a beggar woman seventy-two years of age who had been excessively alcoholic was found one morning completely charred and shriveled to the size of a child's body. Nearly all the soft parts were converted into carbon and ashes, even some of the bones were friable and incinerated. There was no evidence of a conflagration in the place where the body was found. According to experimental evidence an enormous amount of fuel would have to be consumed in order to bring about such complete combustion of the soft parts, including even the large bones. As this could be excluded it seems most rational to accept the old view that the fat of the body surface melts and saturates the clothing, and that this then maintains the flame like a wick saturated with oil.

Dr. Drucker reports a case of abnormal development of the testicle. In a young man of sixteen years the descent of the right testicle began in the thirteenth year; before the twelfth year abdominal cryptorchismus was present, but shortly afterward the patient noticed a hard body in the right inguinal canal. The testicle stuck in the inguinal canal for some time, but in the course of several months the organ succeeded in completing its descent. The abnormality can be detected at the first glance, for the localization of the testicle is unnatural and it is markedly smaller than its fellow. In addition it is hard, less elastic, there is less testicular sensitiveness, and retrograde changes are already going on. At night, after a more or less protracted stay in the recumbent position the gland returns to the inguinal canal, showing that the communication between the scrotum and the inguinal canal is still free, but a hernia is not present. On the other hand, there is a hydrocele of the cord, communicating with the abdominal cavity. By the application of firm pressure a complete

cure may be expected if the channel of communication is of small diameter.

Dr. Huber has described a case of lupus carcinoma occurring in a thirty-year-old charwoman. The affection had persisted for sixteen years. The lupus originated in the nasal cavity and from there spread over the entire face. A lesion of the left cheek is said to have been present for four months, and began at the left angle of the mouth. For five years ectropion has been present. The entire face is occupied by an uninterrupted lupus surface which later ally extends to the ears, almost reaches the scalp above, and downwards encroaches on the neck. In consequence of this there has been cicatricial contraction of the upper and lower eyelids, destruction of the alæ of the nose, and of the nasal septum. On the left cheek is a painful, nodular swelling the size of the palm of the hand covered with offensive shreds and deep red proliferations. The mass exhibits a great tendency to spread. The patient is emaciated, very anemic, and cachetic. On the trunk there is an abortive scrofulous lichen. The submaxillary glands are not palpalable even on the side on which the carcinoma is situated. A part of the carcinomatous area was extirpated and the histological examination confirmed the diagnosis of lupus carcinoma.

Progress of Medical Science.

Boston Medical and Surgical Journal, December 28, 1905.

The Muscle-Splitting or McBurney Incision in Acute Appendicitis, With or Without Abscess: the Course and Result in 75 Consecutive Cases.—L. R. G. Crandon and D. D. Scannell present summarized histories of this series of cases. They claim for the muscle-splitting operation the following advantages: (1) In most cases it is directly over the seat of the disease. (2) It is worth the care to enlarge it properly since even after prolonged drainage we can practically assure the patient that he will have no hernia. From the moment the patient leaves the operating table every movement involving contraction of the abdominal muscles tends to bring together the splits in these muscles and thus close the gridiron; (3) because of this tendency of the wounds to come together, stitches are of almost no advantage, and the surgeon is, therefore, never tempted to omit the safeguard of temporary drainage in doubtful cases. The authors find in the records of the Boston City Hospital for the past twenty-five years notes of 25 hernias through appendectomy scars. Of these 17 occurred through the old-fashioned direct oblique incision, 5 through the right rectus incision, but none through a muscle-splitting incision. The authors follow the technic here described. The skin incision is so made that its middle is about three quarters of the distance from the navel to the antero-superior spine. The incision is nearly transverse—that is, it bisects the angle made by the external and internal oblique muscles as they cross each other. Fibers of the external oblique aponeurosis are recognized, a nick is made with the knife between two fibers and is enlarged by tearing, either with the knife handle or with the fingers. This wound is then held open with retractors. Thick muscle-fibers of the internal oblique are now seen running nearly at right angles to the external oblique. A nick between fibers, as before, is followed by the tearing open of this muscle, as well as the transversalis beneath it, and the properitoneal fat with the two fingers. After good retraction to the full depths of the wound, the peritoneum is lifted between two forceps, nicked and slit open transversely with blunt scissors.

Boston Medical and Surgical Journal, January 4, 1906.

The Physical Aspect of American Football.—E. H. Nichols and H. B. Smith have analyzed the physical injuries sustained by Harvard Football players during the last season, and present several excellent photographs showing injuries received and methods of treatment adopted. The paper is a most valuable one and will doubtless become a classic in the medical history of the game. The authors present the following conclusions: (1) The number, severity, and permanence of the injuries which are received in playing football are very much greater than generally is credited or believed. (2) The greater number of the injuries come in the "pile" and not in the open plays, although serious injuries are received in the open. (3) The number of injuries is inherent in the game itself, and is not due especially to close competition, as is shown by the fact that the proportion of injuries received in games and in practice is about the same. (4) A large percentage of the injuries is unavoidable. (5) The percentage of injuries is incomparably greater in football than in any other of the major sports. (6) The game does not develop the best type of men physically, because too great prominence is given to weight without corresponding nervous energy. (7) Constant medical supervision of the game where large numbers of men are engaged is a necessity and not a luxury, although it is a question if a game, requiring the constant attendance of two trained surgeons, is played under desirable conditions. (8) The percentage of injury is much too great for any mere sport. (9) Leaving out all other objections to the game, ethical and practical, the conditions under which the game is played should be so modified as to diminish to a very great degree the number of injuries.

Puerperal Septicemia.—The histories of two cases are detailed by E. H. Stevens. Both recovered, one being treated by curetting and weak formalin injections and the other, whilst presenting a general septic condition, by antistreptococcus serum. The author summarizes the various methods of treatment as laid down by current text-books. Personally he prefers the long curette followed by the wiping out, by means of a long forceps, of the uterine cavity. He does not see how the advice to use the fingers for this purpose is sound, as a uterus which is from six to ten inches in depth cannot be explored without the introduction of the hand into the vagina, a procedure which to his own mind is vastly more dangerous and less satisfactory than the use of the curette. Fortunately, the milder or putrid type of puerperal sepsis is the most common, and prompt intervention will prevent the disease from assuming its more malignant form.

New York Medical Journal, January 6, 1906.

Water as a Local Anesthetic.—J. A. Wyeth has become convinced that the Schleich method of anesthetic by the infiltration of weak cocaine solutions is due more to the fluid itself than the contained salt. He gives the history of two cases, both men, with small tumors on the back. In both removal was painlessly done under water anesthesia, which acts by pressure on the end organs of the sensory nerves, destroying their sensibility. Ten minims of sterile water were used, the needle resting in the substance of and not below the skin. This procedure was repeated in the same continued linear direction until a sufficient length of anesthetized skin was produced. The needle was then thrust between the capsule of the tumor and the subcutaneous aureolar tissue and the water freely injected so as to lift the skin from the tumor, which was separated also by a similar manipulation from the underlying connective tissue.

The Strenuous Life of School Girls.—W. P. Northrup utters a protest against the forcing methods of modern pedagogy. Each spring there is a resulting crop of neurasthenic girls, worn out by school work. The girls are all anxious to be at the head of their respective classes, overstudy, hurry their meals, or go without breakfast altogether and naturally soon become wrecks. Teachers have little mercy on their pupils, who are goaded to tasks far beyond their powers, and the worst of it all lies in the fact that all this strenuous endeavor is made just at a time when the girl is becoming a woman and entering on her menstrual life. As contributing to unstable nerves, there comes a sequence of impaired digestion, imperfect evacuation of the lower bowel, and an autotoxemia, with all of its injurious effects on the system at large, and especially the nerves. The author renews his plea for the establishment of roof-gardens on city houses. Children must be made to go to bed early. Indiscreet remarks should not be made at the breakfast table by the parents. We should instruct teachers as to the absolute necessity of fresh, cool, circulating air in the schoolroom, and help the girls by kind advice and proper supervision throughout the school year. We must reckon with their ambition, foster it and not kill; guide it and not thwart it, and work together to aid the child to begin and to end its year aright.

The Vicious Circle after Gastroenterostomy.—Under this title J. B. Deaver includes all those cases which suffer from persistent vomiting after the operation referred to. It may be due either to the passage of the contents of the afferent loop into the stomach, or that of the contents of the efferent loop, commonly called "intestinal regurgitation." It is impossible to say in a given case which of the two faults exists. His personal experience embraces five cases in which there was left a long loop of jejunum. All were operated on for the relief of the "vicious circle." In three of them an enteroenterostomy relieved the condition entirely; in one an enteroenterostomy with tying off of the pylorus corrected the condition; and in the fifth it was necessary to do four operations; the first consisted in relieving adhesions at the site of the gastroenterostomy anastomosis, which was followed by temporary relief; a second operation consisted in an enteroanastomosis; a third in the relief of adhesions, and a fourth in tying off of the pylorus. This patient recovered. The author advises that in every gastroenterostomy there should be included an enteroanastomosis between the afferent and efferent loops, thus making sure that no obstruction exists to the afferent loop at the gastricanastomosis. He has abandoned the

Murphy button and employs now the simple suture for both gastric and intestinal anastomoses.

The Difference in the Behavior of Dust from that of Bacteria in the Tonsillar Crypts.—J. Wright notes that there is good presumptive clinical evidence that pathogenic bacteria, which in a state of equilibrium are harmless dwellers in the tonsillar crypts, are under certain conditions absorbed through the tonsillar epithelium. There is fair experimental evidence that pathogenic bacteria of foreign origin, in vast numbers and unmodified by the cellular environment of the tonsillar crypt when blown into the throat of an animal unaccustomed to them, pass through the tonsillar epithelium. In the first instance we must presuppose some antecedent change, some nerve shock, some systemic cause allowing of penetration of the epithelium; in the second, that the foreign pathogenic bacteria, in unusual numbers, overpower the bacteriolytic or other protective influence, normally repelling them. An excellent colored plate in the author's paper shows how carmine granules pass through the tonsillar epithelium from without, while the bacteria remains on the surface. The author has undertaken a series of experiments to determine why the duct or granules pass while germs do not. The granules seem to pass through the viscous layer of bacteria, and then through the epithelium, without carrying any of the bacteria with them. The normal equilibrium existing in the crypt prevents the passing of the bacteria. They may be in the crypt even for a long time, but do not penetrate its epithelium. The viscosity of the bacterium is evidently one of its defensive and offensive properties of a biomechanical nature as distinguished from its biochemical products, the toxine and resulting endotoxine. Evidently also this is the mechanism which combats those auxiliary forces, such as dropping secretions, pharyngeal peristalsis, waving cilia deglutition, etc., by means of which the granules are effectually, and the bacteria ineffectually, kept on the move. Hence we note a tendency to a balancing of the mechanical forces habitual to the tonsillar environment. This equilibrium may be upset by a wound, which carries the germs deep beneath the surface, just as a virulent germ from without or a nervous shock from within may produce a similar result.

Axillary and Pectoral Cicatrices Following the Removal of the Breast, Axillary Glands, and Connective Tissue for Malignant or Other Diseases.—In an illustrated paper, J. B. Murphy summarizes as undesirable sequellæ following mammary amputations and axillary dissections. (1) Fixation of arm to chest with more or less limitation of motion; (2) venous stasis in the arm and forearm with edema; (3) lymphedema of the arm and forearm; (4) neuralgia in either or both; and (5) sensitive retracting scars. The experience of various surgeons is collated with reference to these respective points, and several photographs are presented showing results attained in personal cases. The author describes his own method of operating. When the wound has been closed the arm is dressed at right angles to the body. It is held in this position by an axillary cast extending over the side of the chest and out over the arm to the elbow (figured in the paper). The position is not uncomfortable as one would at first imagine. In his experience the patient suffers less pain than when the arm rests against the pectoral wall. This cast also supports the bar of the axillary triangle and approximates it to the apex. It immobilizes the structure during the process of repair. It can be removed at the end of ten days, when the stitches are taken out. The evil results of fixation are due in a great degree to binding the arm to the chest wall immediately after operation. If a dead space be permitted to exist in the axilla after operation, the cicatrical contraction of its wall will shortly set in and draw the structures in the line of least resistance to fill the space. When the floor of the axilla is a long way from the apex the line of adhesion or contraction is between the ribs and the humerus. This can only be avoided by approximating the base and the apex of the triangle in the days immediately following the operation.

American Medicine, January 6, 1906.

Prognosis in Tuberculosis.—Lawrence F. Flick says the prognosis in tuberculosis depends: (a) On the virulence of the tubercle bacillus; (b) on the dose; (c) on the resistance of the host; (d) on the coexistence of other microorganisms; (e) on the amount of tissue which has been destroyed; (f) on the duration of the disease; (g) on complications arising from toxemias; (h) on age; (i) on race; (j) on social condition; (k) on environment; (l) on financial resources; (m) on temperament; and (n) on character. In forecasting the future of a tuberculous subject the physician should weigh carefully all matters bearing upon the case, and even then should be guarded in his opinion. He should bear in mind that the tendency is always toward recovery, but that there are many impediments in the way of recovery. Restoration to physical health is comparatively easy, but the establishment of a condition of absolute sterility from the tubercle bacillus is difficult. The price of permanent recovery is constant and eternal vigilance and the pursuit of that kind of life which is necessary for recovery. Prognosis should, therefore, always be guarded and conditional. We may assure the patient that he will be restored to physical health and will remain well so long as he takes proper care of himself, but we should impress it upon him that his good health will only continue so long as he does take good care of himself.

Tuberculosis of the Thoracic Duct and Acute Miliary Tuberculosis.—Warfield T. Longcope reports a series of cases which show that the thoracic duct is of great importance as a channel for the spread of tubercle bacilli through the body from the various groups of lymph nodes. Undoubtedly, tuberculosis of the veins and arteries is also to be reckoned as a factor in the rapid dissemination of tubercle bacilli through the body, but is subsidiary in importance to tuberculosis of the thoracic duct and its tributaries. From a study of the cases, Dr. Longcope concludes: Tuberculosis of the thoracic duct is of great frequency in cases of acute generalized tuberculosis. The lesions in the duct from which tubercle bacilli are swept in great numbers through the lymph to the general circulation form the starting point for the generalized acute process. In certain cases of acute generalized tuberculosis, tubercle bacilli may be found in the lymph from the duct, though the duct itself is not the seat of tuberculosis. In a small percentage of cases of subacute generalized tuberculosis the duct may also be affected.

Feeding the Baby.—Ward B. Hoag says the mother's breast, when good, gives ideal results. If well-fed, the baby is good natured, comfortable, has firm muscles, a stable nervous system, the bones are normally developed and he shows a regular increase in weight. Marked deviation in diet, for any considerable period, from that the baby has a right to demand, is bound to produce errors in nutrition. Feeding the baby is not a mechanical process only—simply filling the stomach. Proper growth and development demand definite nutrition. The ability of babies to assimilate food varies; each case presents a personal equation which must be considered. In every questionable case examine the mother's milk for proteid and fat by means of the lactometer and graduated cylinder. Modify the mother's milk by diet and exercise and by giving water to the baby at nursing time. For bottle feeding, good dairy milk and not "one cow's milk," should form the basis of the food. Set "formulas" are an abomination. Begin with the weakest dilution of cow's milk, and increase as the baby assimilates, rather than upset his digestion with a so-called "rational formula" as a starter. Cereal gruels are used successfully in health and disease as diluents of cow's milk. Cane sugar should be used in preference to milk sugar. In making working formulas, the amount of nutrition the baby receives must be known definitely. Alkalies should not be added regularly to the food; rather secure good milk and have it well prepared and kept. Sterilization or pasteurization should be dependent on quality of milk and time of year. Difficult feeding cases are usually the result of bad management. Quantity at feeding and interval of feeding, should be definitely advised. Stomach washing should be employed to promote assimilation.

Priapism in Leukemia.—P. L. Gunckel reports a case in which this distressing symptom occurred. He maintains that the changes which take place in the corpuscular elements in leukemic blood conduce to this condition, and the consequent leucocytosis produces certain changes in the blood-vessels that are concerned in the mechanism of an erection. Of how much importance mechanical pressure by enlarged glands along the course of the nerves, or by pressure upon the veins, may be as a contributing cause in this condition, is not known at the present time.

Journal of the American Medical Association, January 6, 1906.

Diet in Nephritis.—F. C. Shattuck lays down the following as the leading principles pertaining to the dietetic treatment of nephritis: 1. Such control as we may have to-day of nephritis lies in the diet and mode of life rather than in drugs. 2. Such drugs as are useful are so in their effect on the general organism and the heart rather than on the kidneys directly. 3. In all cases of nephritis the main aim is to spare the kidneys unnecessary work, remembering that the urinary system is but one, of the many, making up the body. 4. In acute nephritis, as well as in the acute exacerbations of the chronic forms, Doctors, Diet and Quiet should work together. Starvation for a few days, regulated by the intensity of the process and the strength of the patient, is the keynote here. 5. In the chronic forms the aim is to lighten and to lengthen life. Especially in the contracted form of kidney disease, many years of life and comfort may depend on the physician's skill in adapting sound principles to the particular case and

in securing the cooperation of the patient in persistently carrying out the directions given. Dietary restriction should, in the main, be quantitative rather than qualitative. Alcohol in moderation is not necessarily a poison and may be an aid to digestion. 6. The excess of proteid, not proteid itself, is harmful to the chronically sick kidney. 7. A varied diet is more likely, than a monotonous one, to promote the making of good blood and improving the general nutrition, and that of the myocardium in particular. 8. The amount of albumin is in itself no guide as to the extent of dietry restriction. Shattuck remarks the advisability of a relatively dry diet in dropsical cases, proportioned to the degree of dropsy. In cases of contracted kidney, even without dropsy, he thinks physicians have erred in forcing water, and that the main service von Noorden has rendered is in advocating the limitation of liquids.

Albuminuria in Nephritis and Bright's Disease.—A. Stengel calls attention to the fact that albuminuria is by no means always indicative of permanent nephritis or Bright's disease, unless it is considerable in amount and more or less constant in occurrence. He states that the nature of the accompanying tube casts must not be too greatly relied on to determine the seriousness of the renal lesion, and he states particularly that the occasional or even the frequent appearance of hyaline casts must not be regarded with too much apprehension. Modern methods of centrifugation increase the likelihood of finding casts. Even the definite hyaline cast, as distinguished from the insignificant cylindroids of the mildest grades of renal irritation, is also so frequent in cases of arteriosclerosis, cardiac, or hepatic disease and in gouty conditions, without serious kidney disorder that its significance is comparatively trivial without general corroborative clinical symptoms. He does not underestimate the importance of urinary symptoms, but thinks that the meaning of a trace of albumin is often exaggerated, and that in case of suspected renal disease, frequent examinations of the urine are required and its constant or fluctuating condition should be taken into account.

Cylindruria.—C. P. Emerson says that casts occur wherever albumin might or does occur, but one may be present without the other. It is safe to say that it is the cells that are at fault. The lesion causing cylindruria may be very slight and temporary, some slight disorder of circulation or malnutrition of cells, as renal cells are among the most sensitive in the body. There may be a good index of the present condition of the cell, whether just irritated or totally destroyed, but they give no clue to the underlying conditions. It would seem indeed that the cells of a normal kidney could give a more lively demonstration of their disturbed condition by a vigorous output of casts than could those of a diseased kidney. The latter seems to be able to become accustomed to its condition and gives out no casts. While casts and albumin do not always run roughly parallel, the former are of much importance in following a case of renal disease. Their merely temporary appearance, no matter how alarming in number and variety, means a transient and probably not serious disturbance; their continuance for days, weeks, or months, no matter how few, means chronic nephritis, and for them to remain two years means an incurable case. In nephritis a diminishing number, including fine granular and hyaline casts, means a subsidence of the acute process, while the reappearance of the coarsely granular, epithelial, and bloody casts means a flare up. That they precede albumin in certain early cases of nephritis remains to be proved. In scarlet fever, the casts may outlast the albumin which ceases with the temperature, but in some cases there seems to be only cylindruria from the first and this ceases with the fever. In typhoid, pure cylindruria is not uncommon, and when albumin occurs, casts may become more numerous after its disappearance. Phosphorus poisoning may produce only casts and these abundant epithelial with the cells at all stages of fatty degeneration and fatty casts. Casts also occur in various acute infections, in the cancerous cachexia, in diseases of the central nervous system, in various lung diseases as severe bronchitis and pneumonia, and in empyema. In conclusion Emerson emphasizes the fact that the casts alone are no index to the anatomic renal condition. They are often most marked in non-nephritic conditions, and in the most serious disorders they may be lacking. The more normal the cells the more readily do they form casts when disturbed; in chronic conditions there may be few or none. The duration of their occurrence is important and a case may be well followed by the casts. Epithelial pus and blood casts are more common and of less significance than is generally supposed.

Disorders from Eyestrain.—O. A. Griffin regrets the lack of appreciation of the importance of eyestrain by so many members of the medical profession. The silence of so many of the text-books on internal and nervous disorders is another unfortunate fact, and accounts in part for their common neglect by the practitioner. For the sake of brevity he groups the usual symptoms of eyestrain under the three heads of phenomena of (a) muscular asthenopia; (b) conjunctival and retinal irritation; (c) defective vision. Sensations of dizziness and nausea frequently result from these conditions, though they may also be caused by astigmatism, especially when the axes are at oblique angles. Aside from the direct symptoms of orbital muscular fatigue, congestion and lacrymation, and asthenopia, constant or accentuated by work, the systemic reflex symptoms are of still greater importance, and it is to these that he specially directs attention. A muscular or refractive defect that in one person with ample reserve power may cause few or no disturbances, in another may seriously impair the vital functions, the causal ocular weakness being altogether unrecognized. Thus the ophthalmologist frequently meets cases of chronic headache, gastric disorders, nervous exhaustion, epilepsy, chorea, etc., that have resisted medical treatment but receive permanent relief by the correction of an ocular defect. To illustrate his statements he gives histories of a number of cases of chronic headaches, insomnia, gastric disturbances, neurasthenia, and other nervous symptoms thus relieved in his practice. He notes an increasing interest in the subject as an encouraging indication, but states that there is yet room for improvement, both here and abroad.

The Lancet, December 23, 1905.

Note on the Therapeutics of Unguentum Hydrargyri in a Case of Tuberculosis.—J. T. C. Nash reports the case of a woman, forty-five years of age, who suffered from pulmonary tuberculosis with advanced lesion in both lungs. She also had rectal hemorrhages, obstinate constipation, retroverted uterus, Jacksonian epilepsy of the extensors of the right arm and leg, constant headache and frequent paroxysms of intense agony round the left Rolandic fissure with inclination of the head to the left. It was thought that the symptoms might be due to either anemia or to tuberculosis invasion. The above symptoms, which where marked and severe, after resisting treatment by aperients, iron, and iodide of potassium for many days, were rapidly and remarkably dispelled by the inunction of strong mercurial ointment well rubbed into the groin till the patient was salivated. The nervous symptoms never recurred but the mercurial sequelæ—such as salivation, soreness of the mouth, loosening of the teeth, and loss of hair—caused some discomfort for a time. The remarkable effect of mercury is noteworthy. The severe nervous symptoms quite cleared up. The tuberculous mischief in the lungs became quiescent. Eighteen months later the patient had put on flesh. Ten years later the patient was in better health than formerly. Apart from the complete relief which followed the administration of mercury there was no evidence of syphilis.

The Surgical Treatment of Tuberculous Glands in the Mesentery.—Five cases are detailed by E. M. Corner. Operation was done in all, four permanently recovering and in one, death resulted later from miliary tuberculosis. Ages ranged from six to forty-one years. The author then discusses the relation of tuberculous peritonitis to the cases of caseous mesenteric glands which are suitable for operation. The former disease is recognized in four forms: (1) a dry form frequently with adhesions, (2) a wet form with ascitis, (3) an ulcerative form in which caseous foci are found among adherent coils of intestines, and (4) a suppurative form which is simply one of the former with the addition of pyogenic organisms. Tuberculous mesenteric glands are always found in association with all four forms, but may occur alone. In the former association they are distributed, perhaps scantily, over a large area, but do not form the large movable masses existing in the cases here considered. The latter are the result of tuberculous enteritis and not of peritonitis. The movable palpable masses of caseous mesenteric glands are probably produced in these ways. The palpable tumors of tuberculous peritonitis are formed by adherent coils of intestine or omentum which may contain a caseous focus or not. These tumors are only exceptionally movable. The mobility or fixity of an abdominal tumor becomes a matter of the greatest importance and it is most advisable that the distinction between these two kinds of tuberculous tumors should be made, as the prognosis and treatment are very different. If a caseous focus of tuberculous peritonitis is opened, as it must be occasionally, the results are often extremely unsatisfactory, the patient often ending his life in pain and misery with a fecal fistula, while if suitable cases of tuberculosis of the mesenteric glands are selected for operation gratifying results may be expected.

Some Remarks on the Prevention of Appendicitis.—W. J. Tyson regards the presence of the bacillus coli communis in the bowel as the *sine qua non* of the disease,

but there must be some morbid enteric condition to excite its activity. For an appendicitis there must be some lesion of the appendix to allow the escape of the bacillus, and the latter must be in a state of virulency. Tyson believes that the most prominent cause is constipation. Fecal masses often exist in the various flexures of the bowel even where there is a daily evacuation, and the patient is conscious of no discomfort. As contributing to this the author notes defective masticating teeth, the enormous amount of iced foods now consumed, too quick eating of meals, lack of rest after them, irregularity of eating, etc. All these tend to the lodgment of either fecal masses or of undigested material in the bowel, and these latter furnish the starting point for subsequent trouble. For the relief of the foregoing, the author regards the modern spa treatment with its copious and systematic ingestion of fluid as most advantageous.

Raw Meat Alimentation in Tuberculosis.—R. W. Philip records the results of a series of observations. He found that the exhibition of raw meat was followed by a marked increase in nitrogen retention, even with a diminished intake. Intestinal metabolism was improved, there was a rapid increase in hemoglobin, while digestive leucocytosis (lymphocytosis) was increased, sometimes to more than double that occurring in relation to cooked meat. The following recipes are given for the actual preparation of the meat: (1) Pounded raw meat; that is, finely minced or bruised beef slightly seasoned with salt, served natural, cold or gently warmed throughout, say from a quarter to half a pound, three times daily. The meat should be perfectly fresh; (2) beef juice prepared as follows: extract half a pound of *fresh* meat in half a pint of cold water plus half a teaspoonful of salt for from one and a half to two hours at 35° C. Express the liquid through a cloth. Or the juice may be expressed from the meat directly without the addition of water with more powerful pressure. The meat juice must be freshly prepared for use on each occasion. (3) Raw meat soup prepared as follows: Take half a pound of finely minced *fresh* meat and mix in a bowl with sufficient milk to produce a thick uniform paste. Immediately before serving add half a pint of milk at 60° C.; or the soup may be made in a similar fashion with stock of beef or chicken, or veal, in place of milk.

Ventral Fixation of the Uterus by a New Method.—The operation devised by W. G. Richardson was devised for patients with severe forms of prolapse with cystocele and rectocele, with or without perineal rupture. He finds that often the ordinary perineorrhaphy or colporrhaphy are insufficient owing to a general laxity of the pelvic tissues. Ventral fixation cannot always be relied on, far as usually performed it has for its main object the formation of adhesions between the peritoneal surfaces of the uterus and of the anterior abdominal wall. In course of time these adhesions may disappear, or they may stretch, leaving a dangerous band in the peritoneal cavity. Hence also the uterus again prolapses. There is also associated with the usual method the immediate danger of hemorrhage. The author's method is described in too full detail to be summarized here, and the description must be read in the original paper by those interested. Advantages claimed for it are (1) It is a simple procedure with a minimum amount of bleeding and shock. (2) It can be done rapidly. (3) There is no fear of hemorrhage from needle punctures of the uterus. (4) Patients usually have very little pain as compared with that following the usual methods. They can move in bed and can lie without dragging pain, on either side. (5) There are no sutures to be removed. (6) There is no danger of formation of long bands of adhesions. (7) The uterus is permanently held in excellent position.

British Medical Journal, December 23, 1905.

Remarks on the Value of the Sigmoidoscope in the Diagnosis Between Primary and Secondary Colitis.—P. Lockhart Mummery, in his discussion of colitis, states that, in addition to the information obtained from a microscopic examination of the stools, there should be, whenever possible, a report on the chemical and microscopical characters. The diagnosis of this disease rests upon an examination of the abdomen and an examination of the bowel. A careful digital or bimanual examination of the rectum is necessary in order to exclude any rectal cause for the symptoms which exist. This examination may be made by means of the electric sigmoidoscope. The writer believes that a careful examination of the pelvic colon with this instrument ought always to be made in cases in which symptoms of colitis are present. Cases in which a tumor is situated high up in the bowel can be separated from those in which the cause of the colitis is different. An examination with the sigmoidoscope may also reveal the presence of ulceration. By means of this instrument an exact diagnosis may be made instead of the more or less guess-work method which had to be followed before its introduction. A diagnosis of colitis, which is based entirely upon the symptoms, may be utterly fallacious.

Some Observations on Puerperal Eclampsia.—Reginald Dunlop has recently studied eight cases of eclampsia besides analyzing forty-two others. Forty-two of these fifty cases occurred before the birth of the child. Four of these were during the expulsive stage. The writer calls attention to two clinical types: those occurring in pregnancy and early labor and those occurring during the second stage. In the first class it is probable that the patient has been in the pre-eclamptic condition for some time and the slight additional irritation of the first pains of labor is sufficient to determine reflexly convulsions which were already impending. In the second type, the toxemia may not have been well marked and the strong stimulus of the expulsive pains in the second stage is required to bring about the loss of balance of the cortical centers. The writer believes that if such a case be immediately chloroformed and delivered by forceps the patient will probably have few succeeding convulsions or none. To apply the same treatment, however, to a patient whose labor has not begun or is in an early stage, is adding another risk which is not only useless, but harmful treatment. In these fifty cases edema was present in thirty. But the writer does not consider this symptom a criterion of the imminence of convulsions. One of the most important of the prodromal symptoms is pain in the epigastrium. Epigastric pain was present in six of the writer's eight cases. He describes in one of his cases a clonic spasm which continued for eight minutes by the clock. He is certain that during the whole period of spasm the movements were quite continuous and regular and that there was no interval at any time long enough to allow of natural breathing. He believes that there is nothing to prevent our acceptance of the reports of cases having very long convulsions lasting even twenty minutes. In all of his cases a very rapid involution of the uterus took place, the fundus reaching the brim of the pelvis in one case on the fourth day of the puerperium. The writer emphasizes the importance of saline infusion in the treatment of these cases. In cases, however, in which there is much edema, marked cyanosis with high arterial tension, or much pulmonary congestion, this method should be practised to a moderate extent only.

Remarks on a Case of Detachment of the Retina.—James A. Craig relates the history of this case. Examination of the affected eye showed that the field of vision was defective below, from a point 20 degrees from the fixation point to the periphery. Central vision was unaffected, the patient reading with full correction 6/6. Examination of the fundus revealed the presence of a clearly marked detachment of the retina in the upper quadrant. In his treatment, Craig proved the inefficiency of subconjunctival injections even in conjunction with rigid dorsal decubitus. He then performed evacuation of the subretinal fluid by scleral puncture. The immediate effect was excellent, but in four days the retina again became detached with return of the subjective phenomena. After these procedures had not met with success, the galvanocautery was applied over the seat of operation with the intention of setting up enough adhesive inflammation of the parts to fasten down the retina. After the second trial by this method no signs of detachment again occurred although it is now twenty months since the termination of treatment.

Berliner klinische Wochenschrift, December 18, 1905.

Cryptorchidism.—Katzenstein considers the pathology and treatment of this deformity, which is said to occur in about 30 per cent. of newborn children and in about one per thousand of adults. In spite of its relative infrequency it is stated that over 14,000 individuals were excused on this account from military duty in the Austrain army during the years 1870–1882. In regard to the almost invariably observed imperfect development of the ectopic organ the author expresses the opinion that it is the abdominal situation of the gland which leads to its degeneration, and not a congenital defect. The well-known predisposition of the retained testicle to carcinoma is explained by the author on the ground of its lack of function. In view of the great probability of malignant disease developing in misplaced testicles, the author recommends operative correction of the abnormality in all cases in which a cure has not been effected by massage before the eighth to the tenth year. If a hernia accompanies the retention of the testicle operation is indicated at any age. The statistics of the operations for this condition described by various authors do not present a very encouraging proportion of successful results. Katzenstein describes a new method by means of which he secured a perfect cure in fifteen operations performed on ten different patients. Th

essential step in the procedure consists in the fact that the testicle, after having been freed by careful dissection of the inguinal canal, is drawn down from its position into the scrotum by means of a long dressing forceps carried through an incision made in the lowest part of the scrotum. The gland is then sutured to a small flap of skin which is dissected up from the inside of the thigh and is also stitched to the edges of the scrotal wound. After the vas has been sufficiently stretched by this constant traction, which usually requires at least three weeks, the connecting bridge of skin is cut through and the gland set free from its attachment to the thigh.

A Case of Detachment of the Retina Cured by Operation.—Cohn, in discussing the treatment of detachment of the retina speaks highly of the value of darkness, depletive treatment, and local blood-letting. For the latter purpose the artificial leech of Heurteloup has, he says, fallen into undeserved disrepute, for it is prompt in action, is clean, and readily extracts twenty to thirty grams of blood. Diaphoretics are also of value although subcutaneous injections of pilocarpine are no longer used by the author on account of their weakening effect. In recent times many cures by operation have been reported, Uhthoff, for example, records 8 per cent. of successful results in 337 cases. The author urges repeated sclerotomies as long as any perception of light remains, together with compression, jaborandi, rest in bed and purgatives, and recounts the history of a patient treated in this way twenty-three years ago who has remained cured ever since.

Münchener medizinische Wochenschrift, December 19, 1905.

The Etiology of Eclampsia.—Liepmann publishes the results of a very extensive series of animal experiments undertaken with eclamptic placentas. The material was minced, dried, finely powdered and injected peritoneally into rabbits. As a result of these observations the author comes to the conclusion that the placenta in eclampsia contains a poison not present in the normal structure. This poison is apparently the toxin of the disease, for the more of it the organism has absorbed, as shown by a large number of convulsions, the less of it is to be found in the placenta. On the other hand, the placenta is richer in poison the less of it has entered the maternal circulation. Apparently the chorionic epithelium plays an important part in the formation of this poison, and the placenta therefore appears to be both the site of formation and of distribution of the toxin. The toxin shows a pronounced affinity for the cerebral cells, which are paralyzed by its action and neutralize it. In addition, the poison injures the renal parenchyma, but the liver substance may also be attacked, with the formation of necrotic foci. The injury to the kidney is always a secondary consequence of the poisoning, and if albuminuria already exists it may be markedly increased by the toxin. Both theoretical and practical considerations lead to the conclusion that the best treatment for eclampsia consists in emptying the uterus as promptly as possible, for the expectant plans have given much less satisfactory results. Venesection and intravenous infusion of salt solution are valuable adjuvants, but sudorific treatment by hot packs is directly injurious. In coma or with superficial respiration artificial respiration is of great value; chloroform and narcotics should be used as sparingly as possible. The best results were obtained by chloral hydrate given in 2-grain doses per rectum.

The X-Ray Treatment of Carcinoma of the Esophagus.—Wendel says that although some hope of treating this dire condition surgically is offered by Sauerbruch's development of methods for gaining operative access to the intrathoracic viscera, this method has as yet hardly gotten beyond the experimental stage. So far the best results have been obtained by the use of radium and the *x*-ray. As radium is difficult to procure at present the author tried the *x*-ray in a case of advanced carcinoma of the thoracic portion of the esophagus. The patient was extremely cachectic and could swallow even fluids only with great difficulty. The tumor was ulcerated and had produced an impassable stricture. The *x*-ray was applied through an esophagoscope, carried down to the stenosis. At the same time subcutaneous injections of quinine and sodium arsenate were given. After eight treatments the patient had gained in weight, was able to swallow well-masticated solid food, and no ulceration could be seen. He was then discharged to return at the end of four weeks. Although the result obtained in this case is inconclusive as far as permanency is concerned, the effect of the rays was so favorable that the author urges a further application of the method, and suggests that inoperable carcinomata of the rectum may also be made accessible to the rays through the proctoscope.

Deutsche medizinische Wochenschrift, December 21, 1905.

Dry Iodine Catgut.—Herhold praises very highly the quality of catgut prepared according to the Claudius iodine method, but states that in common with other authors he has found that the material loses greatly in strength on prolonged sojourn in the iodine solution. He describes culture experiments with catgut dried after two weeks soaking in the iodine solution, and agrees with Moschewitz that the material is not only safe *per se*, but is also very difficult to infect. Bits of dry iodine catgut were dipped in pus and laid in agar Petrit dishes. Although some bacterial growth followed, a clear zone all around the catgut remained free from colonies. The author, therefore, considers that the material can safely be used in this form, and describes two types of container in which it may be securely and conveniently stored. Culture tests were also made on catgut that had been soaked in the iodine solution for only three days, and it was found that sterility was secured, so that the author states that in emergencies this length of time is sufficient to obtain safe suture material, though for routine use the ordinary method of preparation is preferable.

The Choice of Operation in Inguinal Hernia.—Baratynski believes that greater individualization is necessary in the choice of methods for the radical cure of inguinal hernia. At present there are two competing operations, that of Bassini and that of Kocher. It is the chief object of the former to effect a reinforcement of the weak abdominal wall, and of the latter to obliterate the peritoneal funnel which forms the starting point of the intestinal protrusion. Kocher's method, accordingly, is not adapted for instances in which there is a serious defect of the muscular structures about the inguinal canal, as it does not offer a very resistant obstacle to relapse. On the other hand when the hernia is still in its earlier stages, if the inguinal canal is not dilated and has an oblique course with fairly normal muscular walls, the Bassini operation involves an unnecessary degree of traumatism in the division of the external oblique and dissection of the cord which it requires. The author believes that before the operation great pains should be taken to ascertain as nearly as possible the anatomical conditions present, and that then the choice of the method to be followed should be directed by the following considerations. If the inguinal region has undergone but little change and the canal is narrow and slanting, conditions that are usually present in the ruptures of children, Kocher's method is to be preferred. In some hernias of medium severity the choice of operation must be governed by the degree of mobility of the peritoneum and the extent of the diastasis between the deep layers of the abdominal muscles and Poupart's ligament. If the peritoneum is redundant and freely movable Kocher's method is indicated; if there is much of a gap between the muscles and Poupart's ligament, Bassini's operation should be done. The latter procedure is also the best in those cases of inguinal hernia in which the inguinal region is markedly abnormal and the canal is dilated.

A Method for Staining Bacteria in Sections.—Saathoff describes the following procedure which he says affords a very simple and rapid method for demonstrating bacteria in sections of tissue. The following formula is given as the most satisfactory: methyl green .15; pyronin .5; 96 per cent. alcohol 5.; glycerin 20.; 2 per cent. carbolic acid, enough to make one hundred parts; filter The sections are put into this solution for two to four minutes and are then washed in tap water until the greenish tinge changes to a purplish one; they are then washed for a few seconds in absolute alcohol which removes the excess of pyronin, and are then cleared in xylol. Oil of origanum should not be used as a clearing agent, as it causes further decolonization of the sections. Protoplasm is stained reddish, and all bacteria including those that are gram negative take a deep red color; the nuclear network is stained blue. If the sections are thick or difficult to stain it is advisable to dilute the stain and let it act for a much longer time. The stain also serves very well to demonstrate intracellular bacteria in smear preparations of exudates.

American Journal of the Medical Sciences, December, 1905.

A Case of Congenital Hepatoptosis, Showing a Mesohepar.—Thomas Wood Clarke and David H. Dolley give a description of this unusual case The point of special interest in its clinical history is the total absence of the accepted etiological factors in floating liver. The patient had never been pregnant, had had no accident, and had not been a heavy worker. Her abdominal walls were not especially lax. Autopsy findings were required to demonstrate this as a case of congenital hepatoptosis. The liver was displaced,

lying entirely on the right side. It had two lobes, an upper, corresponding to the left, and a lower, corresponding to the right. Limited to the upper margin of the upper lobe there was a double reflection of peritoneum to the diaphragm. The liver itself did not touch the diaphragm, and the mesohepar thus formed was thirteen mm. in length. The two peritoneal reflections were united only at their free edges. The lower lobe had no ligamentous attachment. The right lateral and coronary ligaments were entirely lacking. The fissure of the vena cava crossed the left posterior upper extremity of the upper lobe. The writers present the following conclusions: The abnormal position of the liver, with its limited mobility, its atypical shape, the absence of the coronary and right lateral ligaments, the abnormal origin of the left lateral ligament, which assumed the function of the coronary ligament, and of the suspensory and round ligaments, the shifting of the fissure of the vena cava from one lobe to the other, though the course of the vessel was normal, together with other variations, leave no doubt as to the embryonic origin of the condition. Syphilis signs, which were noted in this case, were merely a coincidence. This case must be considered as unique, as a careful review of the literature for the past fifteen years shows no identical one. Although this case does not prove that a mesohepar is the cause of hepatoptosis it does prove Meissner's hypothesis that such a condition may exist.

The Relation of the Lesions of the Gasserian and Posterior Root Ganglia to Herpes, Occurring in Pneumonia and Cerebrospinal Meningitis.—William Travis Howard has been much interested in this subject and has recently examined at autopsy two cases of cerebrospinal meningitis and one case of pneumonia with herpes. In all three of these cases definite lesions were found in the sensory ganglia supplying the herpetic areas. He declares that the cases which he reports furnish additional proof to support the position that the ordinary herpes zoster as well as the herpes of pneumonia and cerebrospinal meningitis is a pathological condition dependent upon definite lesions of certain sensory ganglia, which may be caused by a variety of agents acting in different ways. There is a complete correspondence between the situation of the herpetic lesions and the ganglionic changes. In each case the distribution of the herpes was limited to areas of skin or mucous membrane supplied by the ganglia, which were the seat of the degenerative inflammatory lesions. In those cases with herpes of areas supplied by nerves from the Gasserian ganglion this relation is even more precise. The herpes is dependent upon the ganglionic lesions, and apparently does not vary with causes of the latter. The ganglionic changes in the cases of herpes complicating pneumonia and cerebrospinal meningitis studied by the author are identical with those described by Head and Campbell in their acute cases of so-called spontaneous herpes zoster. In the herpes of meningitis the ganglion changes are probably commonly due to an extension of the inflammatory process along the nerve roots to the ganglia. In pneumonia the matrices morbi are apparently brought to the ganglia by the circulation.

The Nature and the Lesions of Cirrhosis of the Liver, with Special Reference to the Regeneration and Rearrangement of the Liver Parenchyma.—A. O. J. Kelly says in regard to the nature of cirrhosis that it is a chronic focal or localized recrudescing degeneration and partial destruction of the liver parenchyma attended by marked regenerative phenomena on the part of the liver cells leading to the complete transformation of the architecture of the liver and followed by fibrosis. It is not a primary interstitial hepatitis, the changes in the connective tissue being altogether secondary in importance and sequence, probably in large part a replacement fibrosis to fill up potential lacunae left by degenerated liver cells, and probably in some cases at least partly inflammatory. The continuous degeneration and regeneration ultimately lead to a complete change in the architecture of the liver. A specially important factor is the changed circulatory condition both capillary and venous. There is reason to believe that an organ like the liver, although considerably damaged, might be able to establish functional sufficiency were the etiological factor, whatever it might be, corrected or removed earlier than the disease is usually recognized at the present time.

Fatal Obliterating Endophlebitis of the Hepatic Veins.—Alfred F. Hess believes that no case of this disease has been correctly diagnosed. These cases have generally been confused with cirrhosis of the liver. There are present the typical signs of cirrhosis of the liver; ascites with dilated abdominal veins, sometimes a caput medusae, very slight or no icterus, a palpable liver in the early stages, and a palpable spleen. When, however, there is an absence of all etiological cause for a cirrhosis, attention should be directed to the fact, and other features pointing to the disease under discussion should be looked for. If the patient is very young, as is often the case, suspicion should be awakened that one may not be dealing with an ordinary cirrhosis. An important differential diagnostic point is the occurrence of pain over the hepatic area, or localized in the upper abdomen, which is one of the most constant and earliest symptoms of endophlebitis, but exceptional in cirrhosis. The patient with chronic endophlebitis generally states that the swelling of the abdomen has shown itself within a few weeks or even a few days. The writer lays stress upon the importance of post-mortem examination of opening the hepatic part of the vena cava, and examining the ostia of the hepatic veins.

Chronic Anterior Poliomyelitis. George A. Moleen and William G. Spiller describe the case of a man thirty-seven years old, probably syphilitic, who was afflicted with sudden paralysis of the group of muscles innervated by the left peroneal nerve. Complete loss of faradic irritability followed in a week, and this was succeeded by rapid wasting and slight diminution in size of the entire leg. The deep reflexes were present and increased, but not excessively, and in that spinal segment represented by the absolute atrophy they were lost. The symptoms were confined to the left lower extremity and were without change for three months. No fibrillary tremor, sensory disturbance, hand weakness, nor cranial nerve symptoms were present. One year later there was slight general emaciation, complete wasting of the thenar and hypothenar eminences, and, to a less extent, of the interossei muscles; atrophy and paresis of the tongue and pharynx, fibrillation throughout the body, including the tongue, and tendon reflexes still moderately increased. There were no marked electrical changes except in absolutely wasted muscles, and no bladder, bowel, nor sensory disturbances. The patient was becoming more emotional and the illness ended in death. The important alterations in this case discovered at autopsy consisted of the disappearance of many of the nerve cells of the anterior horns of the spinal cord and motor cranial nerves in the medulla oblongata, of the anterior roots of the lumbar and sacral regions, and of the motor nerves of the medulla oblongata, and numerous small hemorrhages in the gray matter, especially in that of the spinal cord. The writers think that this case is one that may properly be regarded as one of poliomyelitis. They believe that the commencement in one lower limb, the paralysis preceding the atrophy, the comparatively rapid development of the symptoms, the absence of sensory disturbances and the pathological findings justify this diagnosis.

Myoclonus Multiplex: With Report of a Case.—D'Orsay Hecht in describing the treatment of this case states that chloral in ten-grain doses by the mouth had a quick sedative action where all other drugs failed, and twenty grains subdued the contractions for several hours. Better than all these in its sedative action was whiskey in one-ounce doses. Given alone it would steady the patient in about thirty minutes and make walking, writing and eating an easy matter. Alcohol added to any of the drugs mentioned acted beneficially when the drug alone proved useless. The whiskey or chloral or both proved to be the only successful agents at the writer's disposal for allaying the myospasms.

Infectious Arthritis: A Bacteriological Contribution to the Differentiation of the "Rheumatic" Affections.—Roades Fayerweather mentions three facts of importance which are to be deduced from the work done in the line of animal experimentation. There is a well established difference displayed by various animals, both among themselves and as compared with man, in their reactions to many organisms. Greater resistance in general is shown by animals as compared with man, more particularly in the case of organisms of slight pathogenicity. A variety of entirely distinct organisms can produce in the joints of animals changes which are indistinguishable clinically or pathologically. The exact reproduction in animals of the lesions in human joints is not to be expected. The writer, as a result of his work, states that evidence from the bacteriological study of acute articular rheumatism shows that the results of the observations of this affection are more at variance than in the less investigated field of infectious polyarthritis chronica villosa. The evidence is in favor of a varied bacterial origin. There is no evidence bacteriologically to show that there is any essential difference between acute articular rheumatism and infectious polyarthritis chronica villosa. The difference in the subsequent course of the two conditions is apparently due to differences in the infecting organisms and in the degree of disturbance they are capable of provoking.

Hematoma of the Sternomastoid Muscle.—J. L. Manasses reports a case in a male child aged two months. There was an irregular enlargement of the right sternomastoid, beginning about 3 cm. from the mastoid attachment. Under daily massage with hot oil the tumor decreased perceptibly and five months later could scarcely be noticed.—*American Medicine.*

Book Reviews.

Biographic Clinics. Volume III. Essays Concerning the Influence of Visual Function, Pathologic and Physiologic, Upon the Health of Patients. By George M. Gould, M.D., Editor of *American Medicine*, Author of "An Illustrated Dictionary of Medicine, Biology, Etc.," "Borderland Studies," "The Meaning and the Method of Life," etc., Philadelphia: P. Blakiston's Son & Co., 1905.

It cannot be gainsaid that Dr. Gould has done no inconsiderable service to the ophthalmologist and to humanity at large by the production of his series of works entitled "Biographic Clinics," chiefly because of his insistence on the influence of errors of refraction in the production of a multitude of symptoms due to disturbances of the central and sympathetic nervous systems. One who carefully reads these volumes, however, must be impressed by the fact that the statements are not always strictly correct and not always just to other writers.

Volume III. is the latest of the series issued. It is a book of 516 pages, containing some thirty-one illustrations. It consists largely of a collection of papers which the author has read before learned societies and which have appeared in medical journals.

Chapter I. is termed "The New Ophthalmology and Its Relation to General Medicine, Biology, and Sociology." According to the argument, the "new ophthalmology" is the study of and the correction of refraction for the relief of "eye-strain." The chapter contains much that is excellent, also not a few expressions that are extravagant. The following are some of the statements in point: "With the exception of *relatively few cases* (italics reviewer's) due to trauma, infections, malnutrition, etc., conjunctivitis and keratitis are of eye-strain origin." . . . "As to iritis and glaucoma, did any skilled refractionist ever see the disease appear in eyes which for years previously had been fitted with right correcting lenses?" . . . "Concerning retinal and choroidal diseases, it is also a truism that they are usually caused by the ciliary strain of uncorrected ametropia" (pages 35-36).

Chapter II., "The Life Tragedy of John Addington Symonds," and Chapter III., "Taine's Ill-Health," are commendable biographical studies. Then follow a chapter by Simeon Snell on "Eye-Strain as a Cause of Headache and Other Neuroses," first published in the *Lancet*, and a chapter by C. Ernest Pronger, read before the Harrogate (Eng.) Medical Society, entitled "Slight Errors of Refraction and Their Influence on the Nervous System." Both of these papers are moderate in tone and present an excellent exposition of the subjects indicated by their titles.

Chapter IV., "The History and Etiology of Migraine," discloses a wide knowledge of the views of various writers on migraine, shows the great divergence of opinion regarding the definition of the affection, and contends, with truth, that a very large percentage of the headaches that are described as migraine are the result of eye-strain due to errors of refraction.

Then follow two chapters, one, "The Optic and Ocular Factors in the Etiology of the Scoliosis of School Children," the other, "Visual Function the Cause of Slanted Handwriting, Etc.," both of which show a careful study of the questions involved and ingenious arguments in support of the writer's contention. Chapters on "Dextrality and Sinistrality" and on "The Pathological Results of Dextrocularity and Sinistrocularity" follow. These conditions are discussed in an interesting and ingenious manner.

A chapter is devoted to the consideration of "Subnormal Accommodation," followed by one entitled "The Reception of Medical Discoveries." The latter occupies fifty-two pages. In this the author reviews the difficulties and trials of those who have discovered new truths and have endeavored to obtain their acceptance by civilized humanity, finds fault with that scepticism which is really rational conservatism, and calls his confrères to account for not accepting his statements without question. The argument presented in the text of this volume is, however, in the main correct.

Surgical Aspects of Digestive Disorders. By J. G. Mumford, M.D., Visiting Surgeon to the Massachusetts General Hospital, etc., in association with A. K. Stone, M.D., Physician to Out-Patients, Massachusetts General Hospital, etc. New York: The Macmillan Company, 1905.

It is frankly stated by the authors in their introduction to this volume that its purpose is to present an estimate of what surgery may accomplish in the diseases of the abdominal digestive organs, excluding here any consideration of the mouth, pharynx, and esophagus. There has been a flood of controversy on this subject, and yet there are but few definite conclusions on hand which may aid the decisions of the practitioner who is more inclined toward medicine than surgery. Particular interest attaches to this book because it is written in combination by a surgeon and an internist. Its component facts are viewed, however, from different, but not from opposing, points of view. The end result is very satisfactory and the book constitutes an interesting and noteworthy effort to contract the gulf which is assumed by many to exist between the two great divisions of medical science. The views which have been agreed upon by the authors, do not savor of extreme radicalism nor is their character dogmatic. The discussion of the subject matter is based on the belief that the duodenum is the central chamber of the digestive apparatus, from both the anatomical and the physiological standpoints, and its diseases are therefore closely associated with those of the neighboring and related organs. The latter assumption may likewise be applied to the other abdominal viscera, so that a broad view of digestive disturbances must take in a consideration of all the abdominal organs. The authors claim, and rightly, that digestive disorders cannot be handled as is done in most textbooks, on an individual anatomical basis, for by this means the involved questions relating to abdominal disease cannot be fully appreciated. The book is written in a pleasing manner, it is sensible and interesting, and will repay being taken into the library of either the surgeon or the general practitioner. It can be especially recommended to the latter for reference in those cases where a doubt may exist as to the propriety of more radical treatment of some obscure and obstinate digestive complaint, and the arguments presented by the writers may help to turn the balance in favor of a possible surgical intervention before this step would be taken too late to do any good.

Gallstones and their Surgical Treatment. By B. G. A. Moynihan, M.S. (London), F.R.C.S. Fully Illustrated. Philadelphia, New York and London: W. B. Saunders and Company, 1905.

Diseases of the gall-bladder, with especial reference to cholelithiasis, are now receiving a degree of attention comparable with that accorded to the equally important subject of appendicitis during recent years. A considerable number of well-known surgeons have devoted themselves to the study of this condition and at the present time quite well defined data are at hand regarding the diagnosis and treatment of gallstone disease. There is no doubt, moreover, that in the future surgical treatment will be adopted more frequently and in an earlier stage of the disease than has hitherto been customary. The great and increasing importance of the subject is therefore believed by the writer to constitute a sufficient warrant for the publication of this large work of over 375 pages. The author has been closely identified with the development of this branch of surgery and is as well known in this country as in England. He bases his book on a course of lectures delivered at the Medical Graduates' College in London and includes a detailed account of the etiology, pathology, clinical manifestations, and operative treatment. The latter is considered in a separate chapter at the end of the book, and presents the most approved methods of procedure now adopted. The book is thoroughly well constructed in every way, the text is concise and therefore easily read, the illustrations are good and largely original. The carefully detailed accounts of the early clinical manifestations of gallstone disease will render the book of especial value to the general practitioner and may influence him to resort to surgical treatment at such an early period of the disease that the patient's chances will be largely improved for a final cure.

International Clinics, a quarterly, by leading members of the Medical Profession throughout the World. Edited by A. O. J. Kelly, A.M., M.D., Philadelphia, U. S. A. With the collaboration of Wm. Osler, M.D., John M. Musser, M.D., James Stewart, M.D., and others, with regular correspondents in Montreal, London, Paris, Berlin, Vienna, Leipsic, Brussels, and Carlsbad. Volume III. Fifteenth Series, 1905. Philadelphia and London: J. B. Lippincott Company 1905.

This set of books is becoming more and more valuable as a library of reference. Almost every subject receives attention in the course of a few years, and it might be well for the editors to give out soon a concise index of subjects covered since the issue of Vol. I. Dr. Johnston of Pittsburg has the first contribution under the department of "treatment" upon the uses of the *x*-ray. It is freely illustrated and gives the results of personal experience in treating cancer and other diseases. The next interesting article is on the practical subject of the "musculotonic and diuretic action of formic acid and the formiates" by Henry Huchard of Paris. This is followed by one on opotherapeutic treatment of renal insufficiency by Teissier of Paris. In the surgical section we have, among others, a long article on fractures of the patella, by Wright of the Long Island College Hospital. Paraffin injections by Broeckaert, ethyl chloride anesthesia, with full bibliography, by Luke of Edinburgh, and many other articles of interest complete the volume.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, December 11, 1905.

THE PRESIDENT, DR. THOMAS E. SATTERTHWAITE, IN THE CHAIR.

Symposium on Pneumonia.—Dr. SATTERTHWAITE, in opening the discussion of this subject, said we were approaching the period when pneumonia promised to be rife in all our cities. We knew that the disease, at times, appeared to take on the character of a dangerous epidemic. In a western city, last season, it had carried off more victims than tuberculosis: in another city where about a thousand cases had occurred, the mortality was upward of 50 per cent. The speaker raised the question of whether or not pneumonia should be a notifiable disease. For many years there had been evidence that it might be, under certain conditions, a contagious disease, but to what extent was it contagious, and under what conditions should pneumonia patients be quarantined? In that connection it would be interesting to know how far this contagious character was observed in the rural districts, or in scattered settlements. Other questions that suggested themselves were, had we to deal with one or several etiological factors? What was the relation borne by pneumonia to occupation, the season of the year, age, and social conditions? Was the disease self-limited? If not, what were the remedial agencies especially applicable to the different forms of the disease?

1. **The Prophylaxis of Pneumonia.**—Dr. JAMES M. ANDERS of Philadelphia discussed this phase of the subject. His conclusions were as follows: 1. Certain degenerative lesions, especially of the cardiovascular system and the kidneys, had shown an increased incidence during the last two decades, and these were found to be associated or antecedent conditions in many cases of pneumonia. Hence, they were probably potent predisposing factors. 2. The indoor conditions during the cold season favored multiplication and propagation of the pneumococcus, and at the same time tended to diminish resistance to infection by the specific organism. 3. The aged were peculiarly susceptible to pneumococcus infection; hence, their bodies should be kept as strong and healthy as possible, especially during the pneumonia season. 4. To overcome the predominating factors of individual predisposition, special attention must be paid to the subject of ventilation, to appropriate clothing, and to the avoidance of agencies that caused degeneration of the heart, vascular system, and kidneys, such as alcohol, social excesses, an over-strenuous business or professional life, and the like. 5. The sputum was the principal source of infection, and should be thoroughly disinfected as soon as it was expectorated, and then destroyed by burning. Public expectoration should be restricted in every possible manner. 6. A large proportion of the general populace harbored the pneumococcus in the nasopharynx, and this was especially true in families and institutions in which cases of pneumonia had occurred: hence, thorough cleanliness and systematic disinfection of those chambers should be carried out during the pneumonia season, more particularly in the case of persons more or less exposed to the virus of the disease. 7. Means to prevent dust from accumulating, and its daily removal from the home and the city streets were imperatively demanded. 8. Public health authorities should be given full executive power to carry out rules and regulations relative to pneumonia, looking to the prevention of its spread, as in the case of other infectious and contagious diseases; they should also carry on a campaign of public education. 9. Measures of prophylaxis must accord with intelligent public opinion before they could be rendered wholly efficient, either by municipal or private authority.

2. **Some Questions in Diagnosis.**—Dr. REYNOLD WEBB WILCOX said the mortality of pneumonia had been markedly reduced during the past six years, practically to five per cent. in private practice, and in order to reduce it still further, an early recognition of the disease was necessary. Supposing, for example, the physician was called to see a robust individual with a chill, or an old person who complained of sudden unaccountable weakness, or a child with a convulsion, followed by pain in the abdomen, or a patient who complained of soreness on one side of the chest or the other, how soon would it be possible for him to determine whether or not he was dealing with a case of acute infectious pneumonia? The temperature, or an examination of the sputum would not help him, nor could he expect to find the classical physical signs at that stage of the disease. In making the diagnosis, he would have to depend largely on minor conditions. A careful examination of the affected side of the chest would show that the pause normally occurring after expiration was shortened, with increased vocal resonance, particularly of the whispered voice, perhaps, over a small area. The affected lung had lost some of its normal elasticity. The heart sounds might be found to be transmitted over a large area, or there might be an accentuation of the pulmonic second sound. Within forty-eight hours the typical signs of pneumonia can be easily distinguished.

In dealing with a long-continued pneumonia, the diagnosis could often be established by the more modern methods of investigation, rather than by the older rules laid down in the text-books, which might be regarded more or less in the light of traditions that had been handed down to us. In differentiating between long-continued pneumonia and typhoid fever, the diminution of the chlorides in the urine on the one hand, and the results of the Widal reaction on the other would often clear up a doubtful case. The speaker also called attention to the fact that in certain cases of cerebrospinal meningitis, the force of the disease seemed to expend itself on the lungs, according to observations which he had made and the results he had reported in 1887. In such cases the low pulse rate, in connection with a high temperature curve; the results of lumbar puncture; the presence of Kernig's sign, and other local symptoms would help clear up the diagnosis. In these cases the difficulties are found in hereditary text-books rather than in actual practice, provided the patient is carefully examined and the results of all methods of examination carefully weighed.

3. **The Present Treatment of Pneumonia as Exemplified by the Routine Treatment of the Disease in Four of the Large New York Hospitals.**—Dr. HENRY P. LOOMIS read this paper. After referring to the fact that pneumonia to-day occupied first place in mortality statistics as the cause of death, Dr. Loomis said that in our large metropolitan hospitals we might look more than anywhere else for the most advanced methods of treatment, as there every new suggestion in therapeutics was tried, weighed, discarded, or adopted. Accurate statistics were kept, thus furnishing data for approximately reliable and impartial conclusions, and all under the critical eye of the young and enthusiastic members of the house staff, who, before their two years were up, were well able to determine the treatment producing uniformly the best results. For the purpose of comparison, the speaker said he had selected the Presbyterian, Roosevelt, New York, and Bellevue Hospitals. He was surprised to find, after investigation, what a uniformity there was in the treatment of pneumonia in these different hospitals. This was not seen in the case of any other disease, with possibly the exception of acute rheumatism. The treatment, briefly outlined, was as follows: Upon admission, the patient was usually given calomel, in small, repeated doses, followed by a saline the following morning. Local applications to the chest were usually restricted to those cases in which there was intense pain and distress. No local applications were made as a routine practice. An exclusive milk diet was adopted during the height of the disease, giving the milk plain or modified. The treatment of the temperature varied somewhat in the four institutions above named. A temperature of 104 and

over was not regarded necessarily as an indication for special treatment, unless it was accompanied by nervous symptoms, marked restlessness, or delirium. Then, at the Presbyterian Hospital, it was treated by the cold pack to the anterior portion of the chest; at the New York, the temperature was controlled by alcohol sponging, or, if that proved ineffective, by the cold pack; at Bellevue, sponging with tepid water (from 80° to 85°) was employed, and at Roosevelt, alcohol sponges or anterior packs. The New York and the Presbyterian Hospitals were the only ones in which tub baths were given in pneumonia, and then only in cases of toxemic pyrexia or in alcoholic cases, with nervous symptoms. Codeine was used to control the cough, ordinarily, in doses of one-quarter to one grain every four hours. Occasionally, heroin, in one-twelfth grain doses, was given, and at times morphine. For the insomnia, which was often a distressing symptom, the drugs most used were trional, veronal, and codeine. Pulmonary edema was treated by hypodermic injections of adrenalin; also by atropine, cupping, and stimulation. Oxygen was not given as much as formerly in any of the hospitals, its use being restricted to cases of dyspnea and cyanosis. The oxygen tank seemed to still hold its place as the actual forerunner of the end. The three cardiac stimulants which were used in all the hospitals were alcohol, strychnia, and digitalis. Of these, alcohol occupied the first place, and most reliance was placed upon it. The indications for these cardiac stimulants of course varied in different cases. At none of the hospitals, with the exception of Roosevelt, was digitalis used to any extent. Nitroglycerin was only used occasionally. At Roosevelt they were using saline injections into the rectum, especially in alcoholic cases and where nutrition was failing. Eight ounces of a normal saline solution were introduced into the rectum through a funnel attached to the end of a catheter. These injections were given once in four hours; they were well retained, and he had been informed by the staff that in many cases markedly beneficial results were obtained. In conclusion, Dr. Loomis said he wished to emphasize the three following points: 1. A plea for the more general use of morphine hypodermically in the early stage of the invasion of pneumonia, a stage which in very many cases was accompanied by not only the shock to the nervous system from a sudden and overwhelming toxemia, but by distressing pain, often amounting to the agony of a pleurisy. 2. If any criticism could be offered of our treatment of pneumonia during the past few years, it was along the line of the injudicious and often unwarranted use of alcohol. 3. The last, and possibly the most important point was that more patients were damaged than helped by the promiscuous drugging which was still too prevalent.

4. **The Treatment of Pneumonia.**—By Dr. Hobart A. Hare of Philadelphia. The chief point in Dr. Hare's paper consisted in his urging that remedies be administered in pneumonia only when very definite and clear indications for their use were present. In many instances, spurred by the anxiety of friends, the physician was inclined to give medicines continually throughout the entire course of an attack of croupous pneumonia, forgetting that remedies which were powerful enough to do good, might, under certain circumstances, be powerful enough to do harm. Further, it should be recognized that our means of treatment could not be curative, but were directed to the support of the system and the regulation of its functions until the disease had run its course. In many instances, rapidly acting, but fleeting circulatory stimulants, such as Hoffman's anodyne and the aromatic spirit of ammonia were all that were needed to bridge over temporary periods of depression. Such remedies were not advantageous when used for a long period of time, as they lost their effects and were apt to disorder the stomach. If digitalis was employed, it should always be a preparation that had been physiologically tested, as specimens of digitalis often varied greatly in their physiological activity. Of the remedies that were used for the purpose of combating collapse and circulatory failure, strychnine and atropine undoubtedly ranked highest, the latter being particularly valuable in those cases in which there was a gaseous pulse, with relaxed blood-vessels. Digitalis often failed, because the heart muscle had undergone degeneration as a result of the toxemia, or because the high temperature of the disease prevented it from exercising its physiological properties. Mild alkaline diuretics, for the purpose of flushing the kidneys, were useful. The writer emphasized the necessity of avoiding medication excepting in the presence of very direct indications for the use of certain drugs. On the other hand, he advocated the free administration of remedies which were indicated to meet special conditions arising in the course of the disease. While on the one hand the physician should not be too active, it was an equally great mistake to be unduly passive in the presence of such a grave illness. Nitroglycerin, which was often used in pneumonia as a cardiac stimulant, was always abused under such circumstances, since it was a circulatory relaxant and never active as a true stimulant. This was a point overlooked by many of the profession. The only indication for the employment of nitroglycerin in pneumonia was when the arterial tension was unduly high, and the heart was therefore called upon to do an excessive amount of work.

5. **The Rôle of Saline Solution in the Treatment of Pneumonia.**—By Dr. J. Madison Taylor of Philadelphia. (See p. 48.)

Dr. Andrew H. Smith suggested the following concept of an average case of pneumonia: Granted that the patient, to begin with, was one of the multitude who had pneumococci on the mucous surface of the air-tubes, and, granted that the conditions had become favorable for their development, a peculiar, specific irritation would be set up, in response to which a peculiar fibrinous exudation would take place into the air-cell. This exudate would constitute a culture-medium exactly fitted for the growth of the parasite, which would immediately begin its multiplication, and the formation of its appropriate toxin. This toxin, being taken up into the blood, would produce systemic effects proportional to its amount and virulence. The exuded material constantly increasing in amount would overflow into adjacent cells and adjacent lobules, carrying the infection with it, until a sufficient area was involved to give rise to appreciable physical signs. The advent of those signs would be earlier in proportion as the observer was a competent auscultator, and was thorough in his examinations. The proportion of toxin in the exudate would increase until the latter became unfitted to act longer as a culture medium, when the further growth of the parasite in that immediate locality would cease. Meanwhile the pressure of the exudate, aided by the coagulating effect of the toxin, would have brought about arrest of circulation in the capillaries derived from the pulmonary artery, and the functions of the part would be completely suspended. The nutrition of the tissues, however, would continue to be provided for by the nutrient capillaries derived from the bronchial arteries, and, having the greater power of the left ventricle behind them, gangrene would be averted. So long as fresh areas of lung were being invaded, so long would the systemic disturbance continue; but when the formation of toxin in the zone last invaded had ceased, there would be a cessation of the general toxic phenomena, and a fall of temperature, marking the crisis. There was evidence going to prove that the crisis was hastened by the formation of an antitoxin in the infected tissue as a secondary process. As soon as the active process in a given location had ceased, a process of repair was set up, in which the nutrient vessels and the absorbents were the principal agents. As the result of this process, the exudate became liquefied and was removed, partly by expectoration, but mostly by absorption. As this was accomplished, the circulation through the functional vessels was resumed, and the part was restored to its normal condition.

Dr. William H. Thompson said that in considering the

mortality statistics of pneumonia in hospital practice, the fact should be kept in mind that many of these patients were not taken to the hospital until after they had been seriously ill for several days. He recalled cases where death occurred within two or three hours after the patient's admission. Another factor that should not be lost sight of, both in connection with the mortality statistics of pneumonia and other infectious diseases that prevailed in epidemic form, was the stage of the epidemic. A striking illustration of this was observed at Roosevelt Hospital during the last epidemic of cerebrospinal meningitis. Of sixteen patients admitted to the hospital during the height of the epidemic, all died but two; of the next series of sixteen, admitted during the abatement of the epidemic, all recovered but two. In all of these the treatment had been practically the same. Dr. Thomson called attention to the fact that on account of the weakened condition of the heart in pneumonia, the strictest instructions should be given to keep the patient perfectly quiet; he should not be raised for the purpose of examining the chest, as even a change of posture might produce cyanosis. The speaker expressed his conviction that the treatment of pneumonia to-day was not as good as it was fifty years ago in the results it gave. We were still compelled to treat the disease symptomatically. We were not giving the antidote to the poison, and until we found that, we could go on talking forever about this, that, or the other line of treatment.

Dr. Beverley Robinson said he had certain fixed notions in regard to pneumonia, but that he would restrict himself to one or two points. In regard to the prophylaxis of the disease he agreed substantially with Dr. Anders. The mortality statistics quoted by Dr. Loomis, which he had obtained from the records of four of the large hospitals in this city, did not furnish a fair indication of the death rate of pneumonia in private practice. It was a well-known fact that many of these patients were not transferred to the hospital until the third or fourth or fifth day of their illness, at a critical stage, and their fright and alarm at being taken away from home helped to overwhelm the much weakened heart. The patient's surroundings and manner and condition of life also had much bearing upon the prognosis, and arterial changes were very common among hospital patients. In a certain number of cases of pneumonia the toxemia was so overwhelming that a fatal outcome was rapid and certain. Others, because of their vitality, or because the toxemia was of a milder form, would recover with the aid of little or no medication, or in spite of all medication. Dr. Robinson said that when a stimulant was indicated in these cases he favored alcohol in the shape of brandy or whiskey, and he emphasized the fact that it should be of the best quality obtainable. Clinically, he believed that alcoholic stimulants deserved a high place in the treatment of pneumonia, and one for which, under certain conditions, there was no substitute. He also placed much reliance upon the proper use of creosote inhalations, not only in the treatment of pneumonia itself, but as a prophylactic measure in severe colds, with threatening pneumonia. Digitalis was also of value in some cases.

Dr. George B. Fowler summarized the result of his experience in the treatment of pneumonia as follows: At the outset, when the patient seems to be getting along well, do little or nothing, excepting to make him comfortable by the use of a hot water bag or bottles, and perhaps, to ease his mind, giving him a mixture of ammonium and the spiritus mindereri. When the time came to allay pain, morphine was given. As cardiac stimulants, when the necessity arose for them, alcohol and strychnia, and sometimes digitalis, was prescribed. We had no specific, no antidote for the disease, and until one was found we had to follow the result of our experience.

Nominations for Officers.—The following nominations for officers for the ensuing years were made: *President*, Dr. Thomas E. Satterthwaite; *Vice-President*, Dr. Ransford E. Van Gieson of the Borough of Brooklyn; *Recording Secretary*, Dr. P. Brynberg Porter; *Chairman for Borough of Manhattan*, Dr. J. Blake White; *Member of the Executive Council*, Dr. Reynold Webb Wilcox.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held November 21, 1905.

Dr. Charles H. Lewis in the Chair.

Carcinoma of the Pancreas with Diabetic Symptoms.—Dr. Lewis A. Conner made this clinical report. The patient was a male, 65 years of age, and was admitted to the New York Hospital September 9 and died October 5. Two months prior to admission he began to lose appetite, strength, and flesh, and was obstinately constipated. No special increase in the amount of urine passed was noticed, although he felt quite thirsty. One month before admission he began to have severe pain in the abdomen, which had been present much of the time since. At the beginning of his illness he weighed 297 pounds; on admission he weighed 178 pounds. After admission the temperature was normal for a few days and then ranged between 99° and 101° up to death. Examination of the blood showed the number of leucocytes to be 30,000. The amount of urine varied from 19 to 64 ounces a day throughout the illness. The first few examinations showed the specific gravity to be from 1.034 to 1.041. There was a trace of albumin, a few casts, 4 per cent. to 5 per cent. of sugar, and a negative reaction for the acetone bodies. On September 16, on rigid diabetic diet, the sugar dropped to 0.7 per cent. On September 22, although the diet was a mixed one, the sugar entirely disappeared and remained absent until death. The patient appeared drowsy and weak, but there were still no evidences of acetonuria. Slight jaundice was present. The liver dullness extended a short distance below the free border of the ribs and the abdomen was still very full despite the loss in weight. On October 2, the jaundice became much deeper, and the liver could be distinctly felt extending to four fingers below the free border and at its edge a small, hard, and irregular nodule could be felt. Just below this was felt and seen a smooth, rounded, elastic mass as large as an orange, which was evidently the distended gall-bladder. In the region of the pancreas neither tumor mass nor tenderness could be made out. Until this date the stools had been constipated and dark colored; then they became clay-colored and contained a large quantity of fat and showed traces of blood. The patient grew rapidly worse and died three days later. The autopsy revealed a large cancerous mass, the size of a large orange, occupying the head of the pancreas, which had ulcerated through the duodenal wall at one point and which had caused complete obstruction of the lower end of the common bile duct and pancreatic duct. Separated from the tumor by a small area of apparently normal pancreatic tissue was a second tumor as large as a small lemon; this occupied the tail of the pancreas. All the bile passages were much distended. The increase in the size of the liver was due chiefly to the distension of its ducts. Several small metastases were scattered through the organ, but otherwise the body was free from secondary deposits. The kidneys showed evidences of chronic interstitial nephritis. The microscopical examination of the mass showed it to be carcinoma which in places conformed to the medullary type but in others contained much fibrous tissue.

The clinical course of this case illustrated in a very striking way the two stages described some years ago by Miralié, *i.e.* an early or glycosuric stage in which the symptoms were those of a severe diabetes plus severe abdominal pain, and a second or terminal stage marked by disappearance of the glycosuria, intense jaundice and great enlargement of the gall-bladder. The reason of the disappearance of the glycosuria in such cases was obscure and difficult to explain.

A Case of Typhoid Fever Complicated by Mesenteric Thrombosis, with Symptoms Simulating Perforation.—Dr.

William L. Baner made this clinical report. The patient was a man, 27 years old, weighing 200 pounds, a pronounced alcoholic, who entered St. Vincent's Hospital on September 27, suffering from typhoid fever and about to enter the third week of that disease. On admission he had a low, muttering delirium, temperature 104°, pulse 110, and respirations 28. The spleen was palpable, abdomen not greatly distended, and the characteristic eruption was noted. A positive Widal reaction was obtained 1-40, and the leucocyte count was 6,000. The patient was given an initial dose of calomel, hot turpentine stupes were applied to abdomen, and the rectal tube was used to relieve flatus. Sponge baths were ordered at 90° when temperature was above 103°. One pint of milk was allowed in twenty-four hours and water given freely. For four days following admission the patient was delirious, with temperature above 104°, reducible about one and a half degrees by bath. With only one pint of milk allowed daily, the casein indigestion was several times shown by curds in the stools, causing temporary withdrawal of the milk. On sixteenth day of disease the administration of half an ounce of castor oil was followed by a large constipated movement, resulting in lessened tympany and temperature and an improved general condition. The ordinary course of the disease until the thirty-second day was followed. In the afternoon of that day the patient complained of sudden tearing pain in the epigastrium, which he said "ripped up" into his lung so he "could not breathe." The temperature was 101°, pulse 110 and rather weak, respirations 32. The fingers were slightly cyanotic and the patient appeared anxious. Following this pain the patient broke into a profuse sweat. Seven hours after the onset of the pain the temperature was 102.6°, pulse 132 and weaker, and the patient was very restless, very thirsty and complained of pain in epigastrium. The leucocytes numbered 20,000. The abdomen was flaccid except for a slight rigidity of the right rectus. The liver dullness was two inches below the free border. The patient was operated on that same night by Dr. J. J. Higgins. A portion of the lower jejunum and upper ileum was found to be purplish and distended with lusterless serosa. There were no constricting bands or mesenteric twistings. About eighteen inches of the affected gut were resected and a Murphy button inserted, and the wound closed without drainage. Patient died same night. Autopsy was not allowed. The pathologist reported that he was unable to actually demonstrate thrombus or other pathological findings in the specimen as submitted, but that the most probable cause of the condition was thrombosis by one of the small intestinal branches of the superior mesenteric artery. The only other possible explanation was a localized paresis of the gut. There were numerous ulcerations in the portion of the intestine removed, some of them so deep that the base resembled tissue paper. In view of the condition of the gut as found at operation and the absence of constriction or twisting, and in view of the sudden pain and the symptoms, it would seem that a diagnosis of thrombosis was reasonably certain.

Dr. Henry W. Berg said that recently he had seen in cases of thrombosis occurring in typhoid fever Widal's reaction in dilutions of 1-180, 1-240 and 1-100. The percentage of agglutins must have been high indeed. Clots were encouraged by higher agglutinating power.

Obstruction of the Pylorus.—Dr. Robert H. Halsey read this paper (see p. 53).

Dr. Edward Quintard said that whenever one met with cases in which an obstruction in the stomach was supposed to exist it was very important to determine the cause of that obstruction because it had such an important bearing upon the question of medical or surgical treatment. In cases of so-called supersecretion washing out the stomach would often cause the condition to disappear entirely. When these retention symptoms were cleared up by frequent washing out of the stomach this hypersecretion would cease. In one case, where there were 1,500 c.c. in the morning (remnants being found two days after meal), the thorough cleansing of stomach, and placing the patient in bed, resulted in marked improvement with an apparent normal gastric juice. He was interested especially in what was said regarding lactic acid and sarcinæ, and it was astonishing how many men to-day held firm to the belief that the presence of lactic acid was a sure sign of malignant difficulty. It was not so at all. Again, it was interesting to note that one may meet with cases in which there are symptoms of obstruction in the stomach and yet the obstruction itself may be distant from that organ. He referred to recurrent intermittent stenosis of the stomach, which was accompanied by a chronic gastritis, which might come on gradually or acutely, and the patient might or might not complain of gastric symptoms. The patient might complain that periodically he had attacks of burning pains, vomiting almost uncontrollable at times, and even water could not be retained. Some of these patients did not vomit more than half the quantity ingested, while others vomited from 1,500 to 1,800 c.c. The functional signs varied greatly. The pylorus became unusually congested, inflamed, swollen, and there was a temporary stenosis of that pylorus. After the vomiting and because the patient could not take food, the tumefaction at the pylorus went down and the opening became normal, or sufficiently patulous for food to pass through. Such patients should be placed in bed and fed per rectum for a day or so, the stomach should be washed out and then these patients will get along all right and require no surgical interference whatsoever.

Dr. S. Suzuki, Surgeon-General, Imperial Japanese Navy, referred to the stomachs of the Japanese, especially the lower classes, and said that with the obstruction there was always dilatation. In many of the lower classes it was found that dilatation occurred without any obstruction at all and this appeared to be more common in Japan than elsewhere, and he believed it to be due to the amount of food that they ingested, that was to say, the volume of the food, but not particularly the weight. The lower classes indulged freely in barley, rice, vegetables, radishes, potato, etc.; as a result there was a large bolus of food which tended to dilate the stomach. He believed that the volume of that organ among Japanese was larger than among the Americans or Europeans. He had seen many post-mortem examinations in which it was noted that the stomachs were from three to four times larger than normal. He referred to a case of syphilis of the stomach, the only one he had seen, which gave symptoms of pyloric obstruction; the antisyphilitic treatment relieved the symptoms. This he believed to be among the rarest of diseases. Pyloric obstruction must be given a fair trial under medical treatment before surgical procedures were adopted. To-day opening the abdomen was not a dangerous procedure if proper precautions were taken, and, therefore, he said he would be inclined to open the abdomen and see exactly what he was dealing with. If an organic obstruction was found which was removable, he would remove it; if this was not deemed advisable, close the abdomen and the patient will have suffered no harm.

Dr. Max Einhorn said that many clinicians thought that continuous hypersecretion did not exist except as the result of organic lesions. There were cases, however, in which continuous hypersecretion was really of a neurotic type and no organic lesions would be found. Pyloric obstruction could be diagnosed before stomach dilatation set in. The important point was, whether the stomach was able to push on the food. In the neurotic type of continuous hypersecretion he said that one always found a more or less large, or considerable, amount of fluid, but without food in the fasting condition of the organ. If such a patient worried a great deal the hypersecretion would continue and instead of two or three ounces being present there would be as much as four, five, or six. These cases were always more or less amenable to treatment. The nervous state of the patient should be allayed, alkalies should be given, electricity could be used with advantage, the treatment being directed more to the nervous condition of the

patient than to the stomach itself. Continuous hypersecretion due to organic lesions was more frequent and in more than one-half of the cases there would be found a benign obstruction of the pylorus; in such cases the hypersecretion was always mixed with the retained food; in such a stomach in the fasting condition would be found a great deal of gastric juice as well as food.

A Clinical Study of Grocco's Paravertebral Triangle.—Dr. Austin W. Hollis presented this paper. He said that Grocco's triangle was a paravertebral patch of dullness situated at the base of the chest posteriorly on the side opposite a pleural effusion; its base was at the level of the twelfth rib and varied in size to 10 centimeters in length, its vertical side corresponding to the median line and usually reached to the level of the fluid. It might be obtained when the patient was in the erect posture or in lying on the normal side, but it should disappear when lying on the side which contained the fluid. The cause of this phenomenon was uncertain. Luigi Ferrannini, from the discovery of a radioscopic shadow of its site, concluded that it was due to local pulmonary condensation caused by a displaced heart. Ewart adduced the theory that fluid in contact with the spinal column on one side would transmit a dull note to the opposite side through the medium of the spinous and transverse processes of the vertebral column and heads of the ribs. Dr. Hollis, from his own observations, regarded this theory as the correct one. At the New York Dispensary and in the wards of St. Luke's Hospital during the past three months he said he had made a careful study of all unilateral pleural effusions and unilateral basic pneumonia to determine the presence or absence of this paravertebral patch of dullness. It appeared from this report of eighteen cases that Grocco's triangle was present in just one-half of the cases. The cases were all serous effusions and included almost every variety in the amount of fluid. In one example with about as small amount of fluid as was possible to recognize, there was no suggestion of the triangle. In two cases with the left chest full of fluid, it was found in one and absent in the other. In the case in which it was found the degree of dullness over the triangle was rather variable. The height of the triangle was as a rule lower than the level of the fluid. In one case, with the chest full of fluid, the apex of the triangle was at the seventh dorsal spine. When the patient was placed on the side of the fluid the dull triangle as a rule gave place to good pulmonary resonance, but this was not invariably so, for in two cases the note remained dull. When the patient was placed on the sound side the dullness was never intensified; on the contrary, it usually became less marked, and in one case the resonance became normal. In six cases of unilateral basic lobar pneumonia, Grocco's triangle was twice found. The dull area seemed as distinct and as well defined as it had been in any of the cases of effusion. The triangle was also found in a case of tuberculous consolidation with thickened pleura at one base. The triangle disappeared when the patient was placed on the affected side. From this series of cases, if their observations had been correct, it would appear to be established that the absence of Grocco's triangle had no value in ruling out the presence of fluid on the opposite side. The presence of the sign might be strong presumptive evidence of fluid on the other side, but that was all. Ewart himself noted a case of right lumbar abscess which produced the sign rather low down, and led him to make the wrong diagnosis of emypema. In one of their cases of pneumonia the very marked presence of the sign made them think of fluid. Whether the sign was also present in free pleural effusions he had not been able to determine; but as fluid seldom collected in a purely unconfined manner it did not seem likely that the disappearance of the dullness when lying on the side of the fluid was necessarily due to the shifting of fluid but might be due to the compensatory emphysema of position, or from intensified resonance caused by the presence of gas in the stomach or colon. The explanation of the absence of the sign in a large percentage of pleural effusion probably lay in the manner in which the fluid collected. If adhesions held the lung against the vertebral column, Grocco's triangle was not likely to be found. Its absence in unilateral basic pneumonia might be due to incompleteness of the consolidation or to the absence of a marked fibrinous exudate in the pleural cavity. The presence of the sign in pneumonia and tuberculous consolidation would seem much against the theory of displaced heart and pulmonary condensation as its cause. The study of this sign had been of great interest to him. He thought that it had been overlooked by most of them because in an ordinary examination they usually percussed at least two or three inches from the spinal column.

Dr. Lewis A. Conner said that Baduel and Siciliano had shown that when the pleural cavaties of cadavers were injected with gelatin to simulate large effusions, and the abdomens were injected to keep the diaphragm in place, by freezing the bodies and making cross sections of the chest, it would be found that there was a considerable displacement of the posterior mediastinum towards the normal side. In his own searches for this sign he had been disappointed in a majority of the cases. He referred to a case seen at the New York Hospital, a very large hydrothorax of the right side, which seemed to fulfil every requirement for the sign; yet not a trace of dullness on the normal side could be elicited.

Dr. J. E. Traub referred to a case he saw fourteen years ago. The patient was a man, 39 years old, and was seen in the second or third day of a pneumonia, the lower two-thirds of the right lung being invaded. He found an area of dullness—not only dullness, but actual flatness. He concluded that it was the result of a marked congestion of the pleura, possibly effusion. A needle was introduced, which withdrew serum filled with blood, three and a half to four and a half ounces being withdrawn. Dr. Robinson, who saw the case with him, remarked that on the left side there was an area of slight dullness close to the spinal column. This case he thought was apropos of the cases under discussion.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Eighteenth Annual Meeting, Held in Louisville, Ky., December 12, 13, and 14, 1905.

(*Continued from page 38.*)

Surgical Treatment of Cancer of the Head and Neck, with a Summary of a Hundred and Twenty-eight Operations.—Dr. George W. Crile of Cleveland, Ohio, in a paper on this subject, presented general conclusions to the effect that since the head and neck presented an exposed field, cancer here, unlike that of the stomach, the intestines, or even the breast, might be recognized at its very beginning; that every case was at some time curable by complete excision; that the field of regional metastasis was exceptionally accessible; that cancer rarely penetrated beyond the extraordinary lymphatic collar of the neck; that the growth tended to remain here localized, and that by freely utilizing all the modern resources of surgery, and by applying the same comprehensive block dissection, as in the radical operation for breast cancer, the final outcome in the surgical treatment of cancer of the head and neck should not only be good, but even better than that of almost any other portion of the body.

Wandering or Aberrant Retroperitoneal Fibroid Tumors of Uterine Origin.—Dr. I. S. Stone of Washington, D. C., stated that these tumors must reach the space behind the peritoneum by way of the broad ligament. This route was the only one open and was necessarily followed by every fibroid which escaped into any part of the retroperitoneal space, however remote. After a fibroid became well separated from the uterus, it usually remained in the broad ligament indefinitely, and would always do so unless other tumors developed in the uterus and were forced to follow

directly in the same channel as the one preceding. It would be observed that single tumors were generally found in the broad ligament and the development of others must occur before we could have the variety we were studying. Many subperitoneal tumors were seen, and few indeed had been noticed where the tumor had lost all connection with the uterus. Such growths could not become parasitic, and receive their nutrition from some other source, as did the intraperitoneal wandering or parasitic tumors. He had no experience with a single wandering tumor behind the peritoneum which had entirely lost its uterine connections, and believed such development an impossibility for the reason mentioned above that a *vis a tergo* must exist. The movement of these tumors was therefore directly opposite to that of the intraperitoneal variety, for the latter must have either movable organs to assist in their progress, or else traction, a result of adhesive contact, must aid in the lifting or elevation of them upward in the abdominal cavity. Dr. Stone reported two cases illustrating the variety he described in his paper. Both of these had grown to very large proportions. In the first, the largest tumor was very high in the abdomen, and was entirely separate from all former uterine connections, even in its blood supply. The presence of a large wedge-shaped middle portion was sufficient proof of the mode of development. It had forced other growths both upwards and downwards, acting as a wedge between the two. In the second case the central portion of the specimen was made up of many small tumors which had appeared to force the larger growths in opposite directions, as in the first case. The largest growth was highest, and was completely separated from the uterus and the tumors below, except by a small amount of connective tissue and by its anterior peritoneal cover. The pelvic tumors in both of these cases were firmly impacted, and in the second case it was impossible to release the specimen without injury to deep and unseen vessels which resulted in fatal hemorrhage. The first patient made a fairly satisfactory recovery, and was able to attend to her duties as housekeeper.

Goiter, with a Report of 182 Operations Upon the Thyroid.—Dr. Charles H. Mayo of Rochester, Minn., said that surgery of the thyroid was increasing. Operations were as satisfactory as any made, giving relief with brief disability. In fifty years the mortality had fallen from 40 per cent. to less than 3 per cent., Kocher's being 2 per cent. Accessory glands, like branchial cysts, were more often found in the lines of hypoblastic inversion. The lymphatics served as ducts. Total extirpation was followed by cachexia in from 50 to 70 per cent. of cases. Graves's disease was probably due to an over- or perverted secretion, the gland showing a general or local condition of cell activity. The great majority of enlargements in young people responded to medication. Part of the benefit obtained in the removal of the sympathetic was from cutting the lymph channels draining the thyroid. During the past seventeen years the Mayos had operated upon 182 thyroids, with 9 deaths. Of these 57 were cases of well-marked Graves's disease, with seven deaths in all, and but one in the last twenty-three. Of these patients 50 per cent. made an early recovery; 25 per cent. did so after several months. The remainder were improved, but had occasional relapses of a temporary nature. Among the remaining 125 operations representing cysts, colloids, parenchymatous tumors, and five cancers, there were but 2 deaths, one from pneumonia, the other from tracheal collapse on the third day following extirpation of a carcinomatous goiter. Cocaine was used in 13 cases, but ether anesthesia preceded by morphine and atropine was the rule. The head was maintained in the high position. The incision was usually transverse. Parenchymatous enlargements and some colloids were extirpated; cysts and encapsulated growths were enucleated. Saline solution was freely given after operation.

The Diagnosis of Renal Calculus.—Dr. Guy Leroy Hunner of Baltimore took up the subject from the general relationships, first considering the various other maladies of the kidney from which nephrolithiasis must be differentiated, and then discussed the diseases of other organs which might mislead the diagnostician. The Röntgen ray and the wax-tipped bougie were considered invaluable aids in the diagnosis of renal calculus, but they both failed at times, and the importance of the urine examination in all suspected kidney cases was emphasized. Several cases were reported to illustrate the difficulties of diagnosis.

Requirements and Qualifications for a Successful Career in Surgery.—The president, Dr. Lewis C. Bosher of Richmond, selected this subject for his address, and said, among other things, that to the recent graduate in medicine no department of his chosen profession appealed with the same force as did surgery. While a student he had been impressed by the brilliancy of the results secured by his professors before his very eyes; at the meetings of the Alumni the clinics in surgery were crowded, while those in other branches were usually either slimly attended or else attended as a compliment to the individual holding them rather than from actual interest in the subject. In most medical colleges the prominence of the professors of surgery in all faculty affairs was well known; while, considering the more material side of the question, he had little trouble in ascertaining that it was no unusual thing for a surgeon to secure for a single operation, occupying but an hour or two, or even less, a fee greater than the entire collections of the general practitioner for a week's steady work, with broken rest and with cares and responsibilities innumerable. On leaving college, if he entered into hospital service, these facts were impressed on him with even greater force, and, later on, having himself entered the ranks of struggling practitioners, the same lessons were borne in upon him with increasing emphasis. Little wonder was it, then, that so many young medical men, bearing all these things in mind, decided that they, too, would enter this alluring field, where they believed they would effect such marvelous results in brilliant cures, in abundant pecuniary reward, in the homage of their fellowmen, and, if moved by even higher motives, in the actual good they might do to suffering humanity. Dr. Bosher called attention to the importance of an academic education. Many a man had attained success in surgery without this advantage, but we were dealing with the rule, not the exception. This academic education should be truly liberal, both in quantity and quality, and should include as many as possible of studies of a scientific nature, especially biology, physics, and chemistry. Of these three branches physics would prove of the greatest use to the surgeon, while biology and chemistry were branches of more actual value to the general practitioner. It was incumbent upon teachers and practitioners of surgery to make it plain to the public that there was a material difference between the trained surgeon and the novice. This education would enable the public to discriminate in a wholesome manner and would ultimately have the effect of rendering it apparent to the candidate for surgical practice that he must properly equip himself before he could stand before the world as a representative of the great surgical art.

Traumatism of the Ureter and Pelvis of the Kidney.—Dr. Rufus B. Hall of Cincinnati, Ohio, read a paper on this subject, in which he reported two cases, and said that the ultimate results were so satisfactory that he hoped they might be of sufficient interest to warrant their recital in detail. The exact location of the injury was not determined in either case. The first patient was a girl, nine years of age; the second, a lad, seventeen years of age. In reviewing the history of the first case, he was inclined to believe that there was a free rent either in the pelvis of the kidney or in the ureter. In the second there was a narrow opening either in the ureter or the pelvis of the kidney, from which urine leaked very slowly at first. In this case rupture had taken place evidently on September 10. It was more than ten days later before urine was extravasated to

make a palpable tumor so that it could be outlined. On November 1 the tumor appeared to be not larger than the boy's head. Both patients were relieved by operation, with drainage.

Aneurysm Treated by Suture Inside the Sac.—Dr. F. W. Parham of New Orleans, La., read a paper on this subject in which he reported two cases treated after the method of Matas. One was an idiopathic aneurysm of the popliteal artery; the other, an aneurysm of the second and third portions of the left subclavian. The popliteal aneurysm was treated by suture, inside the sac, of proximal and distal openings separately, and continuous suture of the groove of the artery intervening. In the subclavian case only the proximal opening was sutured, the distal bleeding being controlled by ligatures. Both patients recovered. The advantages of this procedure were: (1) The practicability of laying open and inspecting the interior of the sac. (2) The possibility of applying a constrictor, clamp, or temporary ligature to the proximal side of the tumor. In the second case reported, the suture was employed because the proximal ligature failed to stop the bleeding completely. The operation of suture within the sac was to be preferred to ligature, because, first, every possible bit of artery was saved except that actually forming the sac of the aneurysm. Second, suture accomplished simple approximation of the intima, and did not cut through as might happen with ligature of an atheromatous artery. Third, all collateral bleeding in the sac was stopped by direct suture of the vessel mouths within the sac, and packing of the sac became unnecessary. Fourth, hence there was no disruption of the outside vascular (collateral) connections of the sac wall, already much relieved by the emptying of the sac. The reconstruction of the artery was to be attempted only in certain cases, as in aortic aneurysm, where suture of the proximal opening would, like ligature, probably be fatal, and in other aneurysms where from swelling and lymphangitis, as in Morris' case, the danger of gangrene was too great to risk any interference with the nutrient stream. In such case reconstruction of the artery might be preferred for two reasons: (1) Because even a temporary continuance of the main stream would be a great advantage until the subsidence of edema consequent upon the evacuation of the sac should have somewhat relieved the stress upon the collateral vessels; and (2) because, as remarked by Matas, and shown in Dana's case, it was feasible at a secondary operation to open the sac again and close the arterial opening. In abdominal aneurysms the method of Matas offered some hope of cure.

Varicosity of the Syphenous Veins with Resulting Varicose Ulcer.—Dr. Robert Carothers of Cincinnati, O., mentioned the operations most commonly employed for the relief of this condition, and among them reference was made to the Schede operation and the Trendelenburg, but he said complete excision of the internal saphenous vein was undoubtedly the most satisfactory operation to be employed, but until the ingenious invention by Charles H. Mayo of two instruments which subcutaneously strip the vein, it was an operation requiring a long incision, tedious dissection, and considerable time for its performance. This operation, as advised by Dr. Mayo, was, that after making a small incision in the upper third of the thigh over the saphenous vein, the vein was located, tied in two places, cut between the ligatures, and the distal end threaded into the enucleator, which was pushed under the skin along the course of the vein for about six to eight inches, where another small opening was made on the instrument and the vein taken out; then the instrument was drawn out from the first opening, the vein was rethreaded into the instrument, which was again pushed under the skin for another six or eight inches, another small incision onto the instrument allowed the vein to be drawn out, which was again ligated and removed. The lateral branches were torn off, and, as a rule, closed themselves. This operation was very quickly and easily performed, but was not without danger from hemorrhage or sepsis. He had twice done this operation and the immediate results were satisfactory. His cases were too recent to say what would be the ultimate result. They were old cases with large, troublesome ulcers treated by skin grafting. The patients were able to leave the hospital in less than three weeks, wearing an elastic porous bandage for support, and were now, at the end of about eight weeks, both at work as housewives. In one case in which there was a troublesome eczema, after an effort for one week to relieve the same, he again followed the advice of Dr. Mayo, sealing the eczematous area with compound tincture of benzoin, until the skin wound had healed.

The Dangers in Scopolamine-Morphine Anesthesia.—Dr. Horace J. Whitacre of Cincinnati, O., read a paper with this title, in which he based his conclusions upon observations made in forty cases of anesthesia induced by this method, upon animal experimentation, and upon a review of all deaths that have been reported in the literature up to the present time: "(1) Scopolamine-morphine narcosis is not devoid of danger. (2) The use of scopalamine-morphine alone for surgical narcosis is not justifiable, and in my experience is not practicable. (3) A single dose two hours before operation lessens the discomforts attendant upon the operative procedure to a high degree, and may obtain a definite place in surgical practice. (4) Four deaths have occurred in a series of twenty-four hundred collected cases which have been so definitely related to the use of this method of narcosis that they are probably scopolamine deaths; this, however, in the absence of autopsy demonstration. (5) These deaths have been reported as occurring with a type picture of alkaloid poisoning and heart failure has been given as the direct cause of death. (6) A fatty degeneration of the liver and kidney has been produced by repeated doses of scopolamine alone, and of the scopolamine-morphine combination, in animals. (7) This method of producing or assisting narcosis cannot yet be recommended for use in general practice, in spite of the great advantage it seems to offer."

Scopolamine-Morphine-Ethyl Chloride-Ether Anesthesia.—Dr. H. A. Royster of Raleigh, N. C., said that of all the combinations suggested for aiding and abetting these agents, that which formed the subject of his paper commended itself to him, because he believed, first, that ether was our safest general anesthetic; second, that ethyl chloride secured the pleasantest primary narcosis; third, that the preliminary use of scopolamine with morphine increased the patient's mental resisting power and lessened the quantity of ether. In his opinion there could be no question of the superiority of ethyl chloride over nitrous oxide gas as a preliminary to ether anesthesia. Its action was more certain and constant and equally agreeable, and he could not help feeling that it was safer. His experience in regard to the combination of morphine and scopolamine was confined solely to the use of these drugs prior to the administration of ether. Of those who had investigated scopolamine, some stated that it was isomeric with hyoscine, others that the effect of the combination was due largely to morphine, still others that the drug was dangerous and uncertain in its action. Its most marked effects were in quieting the nerves and fears, the promotion of an easy courage in beginning the anesthetic, and a prolongation of the restful sleep afterwards. Clinical tests had led him to conclude that scopolamine was not identical with hyoscine, that it did something more than morphine alone, and that it was safe in proper doses. He sounded a note of warning in regard to the use of scopolamine, however, inasmuch as several deaths had followed its employment.

Overlapping the Aponeuroses in the Closure of Wounds of the Abdominal Wall.—Dr. Charles P. Noble of Philadelphia recommended a method of overlapping the aponeuroses which he had used with the utmost satisfaction for nine years, in the closure of all wounds of the abdominal wall, including the Alexander operation, inguinal and umbilical herniæ, diastasis of the recti muscles, appendectomy, and nephrorrhaphy. In but a single case did he know of

a post-operative hernia when the abdominal wound had been closed by this method. When drainage was employed through the abdominal wound, the method was not applicable. The technique of the operation was illustrated by several drawings which demonstrated the method clearly. He closed his article by describing the methods of overlapping the fasciæ employed by Lucas-Championnière and E. Wyllys Andrews in the operation for inguinal hernia.

The Early Diagnosis and Radical Cure of Careinoma of the Prostate, with a Report of Forty Cases.—Dr. Hugh H. Young of Baltimore presented these conclusions, which were drawn from this study of forty cases: Carcinoma of the prostate was more frequent than was usually supposed —occurring in about 10 per cent. of the cases of prostatic enlargement, as shown also by Albarran. It might begin as an isolated nodule in an otherwise benign hypertrophy, or a prostatic enlargement which had for many years furnished the symptoms and signs of benign hypertrophy might suddenly become malignant. Marked induration, if only an intralobular nodule, in one or both lobes of the prostate in men past fifty years of age, should be viewed with suspicion, especially if the cystoscope showed little intravesicular prostatic outgrowth, and pain and tenderness were present. The posterior surface of the prostate should be exposed as for an ordinary prostatectomy, and if the operator was unable to make a positive diagnosis of malignancy, longitudinal incisions should be made on each side of the urethra, as in prostatectomy, and a piece of tissue excised for frozen sections, which could be prepared in about six minutes and examined by the operator at once. If the disease was malignant the incisions might be cauterized and closed, and the radical operation performed. Cancer of the prostate remained for a long time within the confines of the lobes, the urethra, bladder, and especially the posterior capsule of the prostate remaining inviolate for a considerable period. Extraprostatic invasion nearly always occurred, first, along the ejaculatory ducts into the space immediately above the prostate between the seminal vesicles and the bladder, and beneath the fascia of Denonvilliers. Thence the disease gradually invaded the inferior surface of the trigone and the lymphatics leading toward the lateral walls of the pelvis, but involvement of the pelvic glands occurred late, and often the disease attacked by metastasis the osseous system without first invading the glands. Cure could be expected only by radical measures, and the routine removal of the seminal vesicles, vasa deferentia, and most of the vesical trigone with the entire prostate, as carried out in four cases by the author and fully described by the illustrations, was shown to be necessary by the forty cases, including eight autopsies and ten operations. The four cases in which the radical operation was done demonstrated its simplicity, effectiveness, and the remarkably satisfactory functional results furnished.

(*To be continued.*)

Chicago Medical Society.

At a meeting held November 29, 1905, Dr. Ramon Guiteras of New York read a paper, by invitation, entitled "Etiology, Diagnosis, and Treatment of Perinephritic Abscess." He emphasized the following conclusions: (1) Many more cases of perinephritic abscess were due to suppurative renal disease than was generally supposed. (2) Traumatism, exposure, and similar influences to which perinephritic abscess was attributed were not so important as many observers had claimed; they were vaguely given as causes when they were simply coincidences, or the active cause of rupture of already existing abscesses of the kidney or neighboring structures. (3) It was important, though difficult, to determine the source and course of the pus; therefore, during the operation the surgeon should try to determine whether the kidney was the source by all the latest methods of modern diagnosis, and if not, what tissue was the source. It was important to discover the route taken by the pus, as it indicated where counter-incisions should be made; and the further treatment of the complications of the case. (4) The elements of success in operations for perinephritic abscess might be summed up as: (a) Early operation, incision, and evacuation before the pus had time to burrow extensively; (b) thorough exploration without timidity, opening the kidney and exploring the ureter, if need be; (c) thorough drainage down the deepest part of the sac by means of large rubber drains of gauze, the drain being kept in place until a well-formed sinus existed down the deepest part of the cavity; (d) secondary nephrotomy or nephrectomy, if indicated at the time of the operation, later. (5) Nephrectomies were exceedingly dangerous in these cases, and it was better to perform nephrotomy or to content oneself with opening the abscess cavity even though a sinus resulted. Dr. G. W. Holden of Denver discussed the "Sanatorium Treatment of Tuberculosis in Colorado," with especial reference to the Agnes Memorial Sanatorium, with which he was connected. His report covered but one year, the first of the institution's existence. He said forced feeding was not essential nor desirable to obtain results; he preferred to depend upon an abundance of good food served in the three regular meals in conjunction with the careful regulation of the diet of the patient. Constant attention was paid to assimilation and elimination. Dr. Arnold C. Klebs analyzed "Behring's New Tuberculosis Remedy." Only a few essential conclusions could be drawn from the ambiguous wording of Behring's address at the recent International Tuberculosis Congress. He said that Behring had, by certain chemical methods, isolated from the body of the tubercle bacillus a substance which he called TC. This substance constituted the life principle of the tubercle bacillus, and had, when introduced into the cell body, protective and curative properties, distinctly superior to those exerted by his bovovaccine (living tubercle bacilli). Dr. Klebs saw in Behring's adoption of the theory of the presence of a *matière vaccinante* in the body of the bacillus a decided change in Behring's opinion and a vindication of Edwin Klebs' persistent adherence to and proof of this hypothesis. He believed that Behring's new method followed in general the same lines as those established by his method of cattle immunization, with the exception that there the TC representing the life principle of the bacillus was introduced instead of, as here, the living attenuated bacillus itself. Behring's hypothesis of a cellular immunity, different from the antitoxic immunity, was then analyzed in the light of recent and older investigations on the effects of infective and toxic agents on the normal cell life. He did not think that in this direction Behring had discovered anything essentially new, but had adopted the theories of Metchnikoff and other investigators. Dr. J. W. Pettit of Ottawa, Ill., discussed the "Economic Aspect of the Modern Treatment of Tuberculosis," saying that it was primarily based upon life in the open air. To meet this demand the radical departure from the conventional plan of hospital construction was necessary. He strongly advocated the use of tents and referred to the success that had attended efforts directed toward the treatment of this disease at the Ottawa Tent Colony. Since the tent was practicable in a cold climate, it should be used more extensively. It fulfilled the conditions most perfectly from a scientific standpoint. A tent was an ideal method of housing tuberculous patients in a mild climate. The cost of food was the most expensive item in the treatment of tuberculosis, and any attempt to cheapen this feature by cutting down the quantity or cheapening the quality would tend to nullify the treatment just to the extent to which this was done. The psychical element must be also considered. This made it necessary to provide certain forms of amusement and recreation, which added somewhat to the expense.

For fifteen years no suicide of a Jew was recorded in the seven great districts that comprise the most populous part of central London. But of late there have been several cases.

Pathological Society of Philadelphia.

At a stated meeting held December 28 Dr. A. G. Ellis presented a communication entitled "Congenital Malformation of the Heart" and he exhibited a series of illustrative specimens, including perforate auricular septum, perforate ventricular septum, transposition of aorta and pulmonary, persistence of ductus arteriosus, stenosis of the pulmonary artery. Dr. Canby Robinson exhibited specimens of "Aneurysm of the Heart." The one represented a saccular dilatation of the wall of the left ventricle resulting from obstruction of the coronary artery, while the other took the form of a dissecting aneurysm. Dr. J. C. da Costa, Jr., read a paper entitled "Iodophilia: A Study of One Hundred Cases." Observations were made on a series of patients suffering from a variety of acute febrile disturbances, and in general the morbid condition was found in association with states dependent upon some form of toxemia or other and not in any way related to leucocytosis. Dr. H. M. Snyder read a paper entitled "Eosinophilia in Amebic Dysentery," reporting a case of dysentery in which amebæ were found in the intestinal discharges, together with eosinophile leucocytes, which also were found in the blood in considerable number. The lesions in the rectum were disclosed with the aid of the proctoscope. Dr. D. Riesman exhibited specimens of contracted kidneys, with hypertrophy of the heart and constricted aorta and edema of the lungs together with subpleural extravasations of blood. The patient had died suddenly from pulmonary edema of rapid development. Drs. E. R. Butt and C. J. Hunt reported a "Case of Puerperal Sepsis with Tricuspid Endocarditis." The patient was a young woman who had suffered an abortion with infection and secondary invasion of the endocardium of the right side of the heart.

Philadelphia County Medical Society.

At a stated meeting held December 13 a symposium was held on "Disorders of the Circulatory Apparatus." Dr. Alfred Stengel read a paper entitled "Arteriosclerosis as a General Disease." He divided the affection into three stages, a primary stage difficult of recognition, with vague and indefinite symptoms referable to the circulatory apparatus; an intermediate stage, with obvious physical signs and clearly defined symptoms; and a terminal stage, attended with infections and a fatal issue. He recognized also thoracic, abdominal, cerebrospinal, and other types of the disorder. The greatest care is required not to mistake the general disorder for that of a viscus or tissue. Dr. Wm. H. Welch of Baltimore presented a communication entitled "The Relations Between Cardiac and Renal Disease and Arteriosclerosis." He pointed out the connection between these three groups of affections, and he dwelt upon their frequent origin from common causes. On the other hand any one may have an individual origin and perhaps lead to the development of the others. Dr. Judson Daland read a paper entitled "Myocarditis Independent of Arteriosclerosis." He dealt with the various forms of inflammation and degeneration of the myocardium arising from a multiplicity of causes, but not rarely associated also with changes in the walls of the blood-vessels. Dr. H. A. Hare read a paper entitled "Remarks on Cardiovascular Disease, with Reference to Treatment." The discussion was participated in by Drs. J. C. Wilson, G. E. de Schweinitz, W. B. Stanton, J. H. Musser, S. Solis-Cohen, and A. O. J. Kelly.

The Supporters of Quacks and Medical Heretics.—Our "educated" or "literary" classes are as much the natural prey of every charlatan as minnows are the natural prey of a pike. We have seen the wife of an English ambassador energetically supporting the pretensions of one of the worst of the tribe of cancer quacks. We have seen an English prime minister declaring the efficacy of vaccination to be an open question.—*The Lancet.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 30, 1905.

	Cases	Deaths
Measles	798	12
Diphtheria and Croup	388	38
Scarlet Fever	183	6
Smallpox	..	..
Chickenpox	117	.....
Tuberculosis	365	163

Cerebrospinal Meningitis	36	16
Typhus Fever	.....	.....
Yellow Fever	.....	.....
Cholera	.....	.. ..
Totals	1,932	242

Mosquito Bites.—Schill, after trying many different agents, found that bicarbonate of sodium and thymol were the most effective remedies to relieve the irritation of mosquito bites. The first is either applied directly to the bite, moistened with enough water to form a paste, or is painted on in a saturated solution. The thymol is applied to the face, neck, and hands in 50 per cent. alcoholic solution, and is very effective in keeping the insects away.—*Schweizer Wochenschrift für Chemie und Pharmacie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended January 6, 1906:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
California, San Francisco	Dec 16–23	3	..
Florida, Jacksonville	Dec. 23–30	5	..

IMMUNIZATION IN TUBERCULOSIS.

WITH ESPECIAL REFERENCE TO THE METHOD OF PROFESSOR VON BEHRING.

BY KARL VON RUCK, M.D.,

ASHEVILLE, N. C.

WHEN Prof. Koch, in 1890, introduced tuberculin, he did not attribute to it an immunizing action; he considered its effect to be due to a specific toxin which he believed caused necrosis and eventual expulsion of tuberculous material. Neither did subsequent experiment with this preparation show any considerable degree of immunizing power, although the temporary protection against second infection in Koch's preliminary animal experiments suggested such an effect.

Prof. Rindfleisch,[1] upon grounds of histological studies, was one of the first to question the necrosing action of tuberculin and concluded that its action was an immunizing one. Petruschky[2] claimed an immunizing action from clinical observations; Hueppe[3] made a similar claim of specific stimulation for the remedy, by which the tissue cells were enabled to destroy the tubercle bacillus; Pfuhl[4] and Bujwid[5] were able only to prolong the life of the experiment animals for longer periods after infection, as compared with the controls. Doenitz[6] and Sattler[7] obtained a protective influence in experimental eye tuberculosis in rabbits; Kitasato[8] actually succeeded in curing tuberculous guinea pigs with tuberculin and found that they were protected against new infection.

The general consensus of opinion, however, was, and continued to be, that the action of tuberculin upon tuberculous tissue is in the nature of an irritant toxin which causes the peculiar reaction phenomena which were considered specific by most authors and which, when within safe limits, tend to healing processes, which were demonstrated by Kromeyer,[9] Doutrelepont,[10] Ziegler,[11] Cheyne[12] and many others.

Efforts at immunization had, however, been made prior to the introduction of tuberculin. In 1883, Babes, Cornil and Leloir used for this purpose attenuated tubercle bacilli for vaccination against lupus; and Cornil and Babes tried to protect rabbits by injection of tuberculous material. Charrin in 1885 tried a method of successive inoculation in guinea pigs, hoping that the virus from the same animals upon second or repeated inoculation would arrest or impede the tuberculous process. In 1887 Daremberg used spinal cord substance from tuberculous animals for protective inoculation, but all these methods proved of no value.

After the introduction of tuberculin by Prof. Koch, various efforts followed to obtain the specific toxin in a purer form, or in larger quantities, than it was believed to be present in his preparation. This led to efforts of its purification, especially by Prof. Koch himself, by Hunter, Klebs, Trudeau and others, and likewise to a study of the action of dead tubercle bacilli, and to the extraction of their bodies with water, glycerin, alkalies, acids, etc., in the hope that these direct extractives would prove of more value than the crude tuberculin with its admixture of pepton, meat extracts, and glycerin from the liquid bouillon cultures.

Hueppe and Scholl[13] were probably the first to extract tubercle bacilli with glycerin, but the extractive so obtained proved of no advantage in their hands. Jeffries[14] used alcohol, ether, benzol, chloroform and later glycerin extracts. Zülzer[15] extracted tubercle bacilli with hot hydrochloric acid solution, obtaining what was supposed to be an alkaloidal principle in the form of a white crystaline salt. Wey[16] extracted them with caustic soda and isolated a protein substance which he called toxomucin. Hammerschlag[17] in his studies during 1888 and up to October, 1890, had already found that cultures of tubercle bacilli contain a toxic albuminous substance, and that from the bodies of tubercle bacilli could be extracted a large amount of fatty substance soluble in alcohol and ether, which exceeded greatly the amount obtainable from the extraction of other bacteria; one of his analyses showed 28.2 per cent.; later de Schweinitz and Dorset[18] obtained as high as 37 per cent., and larger percentages of fats have been claimed since.

In the meanwhile the study of the action of dead tubercle bacilli by Koch,[19] Prudden and Hodenpyl,[20] Strauss and Gamaleia,[21] Abel,[22] Vissmann,[23] Mafucci,[24] and others had brought additional evidence that the bodies of tubercle bacilli contained a specific toxin, but as no one was able to obtain it in an available form, dead tubercle bacilli themselves were used, with the expectation that the living organism would itself extract the toxin, and that thus artificial immunity would occur.

In some instances a certain degree of immunity appears to have been attained, but on the whole the results were unsatisfactory, as were also the experimental trials with dead tubercle bacilli upon guinea pigs in my own laboratory by Prof. Klebs and myself. Apart from the failure of completely protecting the animals against infection, the extremely slow absorption, and the frequently observed necrotic changes and abscess formation at the point of injection of the dead tubercle bacilli appeared to me to exclude their clinical application in man, in which we had further to take into consideration the formation of histological tubercle in the lungs and other organs which had been found to occur in animals, especially when the bacilli were purposely or accidentally introduced into the blood or into the trachea.

By the use of living avian tubercle bacilli, known not to be infectious to man, Trudeau[25] in 1892

succeeded in producing artificial immunity in rabbits to such a degree that subsequent inoculation with human tubercle bacilli into the anterior chamber of the eye did not produce a typical tuberculosis, whereas in the control animals such inoculation led to the destruction of the eye.

De Schweinitz[26] succeeded in the production of unquestionable immunity in guinea pigs by injection of attenuated living tubercle bacilli in 1894, thereby preceding von Behring by many years in the principle of the latter's discovery of bovovaccine, or "Jennerization" for cattle.

Enough has been stated to indicate the status of immunization against tuberculosis at the time when Prof. Koch[27] in April, 1897, introduced tuberculin R. which he had shown to possess a distinct immunizing power that was afterward confirmed by animal experiments of others. Up to this time no one had, to my knowledge, made efforts to liberate the specific toxin contained in tubercle bacilli, except by the various extractions mentioned; Prof. Koch was the first to attempt this by reducing the bacilli into an impalpable powder in an agate mortar, presuming that in this manner it would be present in solution in his tuberculin R. This subsequently was shown to be otherwise, since when tuberculin R. was filtered through porcelain, the filtrate proved inactive and the amorphous powder of tubercle bacilli remained upon the filter. The bacilli were not even as finely broken up as was believed by Prof. Koch, for isolated, perfect specimens and even clumps of adherent bacilli could be shown present on microscopical examination of his preparation. Nevertheless the tubercle bacilli were sufficiently divided by grinding, and the adherent clumps were sufficiently eliminated by centrifuging that no such troubles occurred at the point of injection, as had been witnessed from injection of dead tubercle bacilli not so prepared, and while in its clinical application some authors obtained better results from tuberculin R. others found the preparation less reliable and less certain in its action, indicating at times a cumulative effect by severe and unexpected reactions and complications arising during its use.

Many complained of the inconstancy of its action soon after its introduction, as for instance Woerner,[28] Baudach,[29] De la Camp,[30] Doutrelepont,[31] Herzfeld,[32] Rossmann,[33] Spengler,[34] Van Horn,[35] Jez,[36] Raw and Abrams,[37] and Reinhold.[38]

Another danger from its use was soon shown to exist by Treudeau[39] who found living, virulent tubercle bacilli in the preparation, after I had myself[40] directed the attention of the profession to the probability of such an occurrence.

Trudeau was apparently confirmed by Schroeder[41], and when the new tuberculin emulsion was examined by Thellung[42] and Niessen[43] they again found occasion to enlarge upon this dangerous feature of the remedy, which was impossible to avoid by the method of its preparation from living, virulent bacilli.

I have heretofore stated that Prof. Koch was the first to seek the liberation of the immunizing substance from tubercle bacilli, which he did by powdering them and thereby he at least facilitated their extraction within the tissues after their injection.

The preliminary removal from tubercle bacilli of substances which hinder the liberation of the immunizing toxin, with the specific purpose of rendering the latter readily available for therapeutic use, I believe to have first been resorted to by myself.

While Prof. Koch was engaged in the production of his tuberculin R., I worked in another direction upon the theory that the large quantities of fatty substances contained in the bodies of tubercle bacilli hindered the extraction of the otherwise soluble toxin both in vitro and in the tissues. By this theory, to which I have since referred in an editorial,[44] and again in an article on fever,[45] published in the *Journal of Tuberculosis*, I could account for the but slight degree of immunity which resulted from the use of the various tuberculin preparations and of dead tubercle bacilli, as well as for the failure of natural immunity in the course of the disease.

The occurrence of natural immunity appeared to me to be further prevented by the enclosure of the bacilli in the nonvascular tubercle often caseous or surrounded by connective and fibrous tissue, or both, since under such conditions the absorption of the immunizing substances from tubercle bacilli additionally so protected, would have to be extremely slow and uncertain if it occurred at all.

Once this theory conceived, the further I considered it the more plausible did it appear, and I immediately acted upon it, first washing the tubercle bacilli upon a filter until the filtrate gave no longer a biuret reaction, and then as completely as possible extracting their fats.

Although previously washed with water until nothing more could be extracted I found that after the extraction of the fats, the tubercle bacilli yielded a considerable amount of organic substance when they were now again extracted with distilled water. With this last water extractive, animal experiments had been undertaken and some of them were still in progress when on May 6, 1897, I communicated the result of my work as far as it had progressed, to the American Climatological Association,[46] at Washington, D. C., and there demonstrated the preparation of tubercle bacilli in the various stages of extraction as well as the extractives obtained, including the final extract with distilled water in different degrees of concentration, and likewise the residue of tubercle bacilli which yielded nothing more.

I likewise claimed immunizing power for my preparation upon ground of my animal experiments, inasmuch as the control animals had all died, whereas the animals which after infection were treated with the remedy were all living and progressing favorably.

In a paper read before the Academy of Medicine in Cincinnati, on December 20, 1897,[47] I reported the final outcome of the experiments, showing a complete cure of at least one of the experiment animals, inasmuch as only fibroid nodules were found which microscopic examination proved free from caseation and from tubercle bacilli, and tissues from these nodules implanted had failed to cause infection in guinea pigs.

In these early experiments the doses employed and the duration of the treatment appeared to stand in close relation to the results.

A subsequent series of experiments upon six guinea pigs, with a view of protective inoculation prior to virulent infection, was made in 1898, but the work was not published at the time, because no final autopsies were obtained for reasons to be stated below.

These animals were treated for six weeks with much larger doses than had formerly been employed, and were infected two weeks after the preliminary treatment was completed, together with a like number of controls. The latter all died in the course of four months, and their autopsies showed the usual tuberculous lesions

in glands, liver, spleen, lungs, etc., whereas, the protected animals lived without signs of tuberculosis, and a second infection in September, 1898, again failed to cause evidence of disease. All these six animals were living and apparently in good condition in the spring of 1899, when they were accidentally killed in their kennel by a dog, and were disposed of by a servant, without the facts coming to my knowledge, the accident happening during my absence from home.

Although lacking the absolute proof of autopsies, the results in these animals were nevertheless convincing to me personally, but well aware that the results of animal experiments need to be supplemented clinically, I continued to devote myself to the therapeutic use of the remedy and to its clinical study upon patients.

My efforts in obtaining the immunizing toxin from the bodies of tubercle bacilli by previous removal of substances which hinder or prevent its liberation were, so far as I know, next followed with apparently the same object in view by Prof. von Behring in 1898. In his paper before the Congress for Hygiene and Demography at Lisbon,[48] on April 12, 1898, he described a method, consisting of washing, and the extraction of fats from tubercle bacilli, prior to the final extraction of a toxin in glycerin and water. This latter extraction was, however, accomplished in an autoclave at a temperature of 150° C., a degree of heat which, if it did not actually destroy it, must have seriously modified and injured this toxin, a fact which was admitted by von Lingelsheim,[49] who appears to have done the work under Behring's directions. I am not aware that this preparation has ever been employed in the treat ment of tuberculosis.

Since Prof. Koch introduced tuberculin R. many have continued to experiment with various new and old tuberculin products while others have looked for the best results from the use of animal sera. Among these Maragliano,[50] who has been the chief exponent of serotherapy in tuberculosis, immunized first with tuberculin and later with a watery extract from unprepared tubercle bacilli, which he obtained by heat of between 90° and 100° C. and by subsequent concentration of the filtrate.

As my purpose is more directly concerned with the question of direct immunization, I have no space for a review of the interesting literature on the treatment of human tuberculosis with sera derived from animals.

The efforts to induce immunity in animals from the use of living tubercle bacilli, as those already cited by Trudeau, the success in immunization by de Schweinitz in 1894, or later by von Behring, the experiments by Moeller and Friedmann in immunization with the pseudo-tubercle bacilli of cold-blooded animals, have all added to the interest and understanding of the subject.

New tuberculin preparations have also appeared and much was expected from Buchner's Tuberculo-plasmin,[51] which he obtained from tubercle bacilli under hydraulic pressure of 300 to 400 atmospheres. Hahn,[52] who with Bulling studied this preparation experimentally says in his article on natural immunity,[53] that they could not obtain an unquestionable immunity with this substance.

Vesely[54] made a new modification of the old tuberculin, by leaving out of the culture fluid the beef extract and adding more glycerin, and found this preparation to give him better experimental and clinical results. The modification by Denys,[55] and from which he reported excellent results, consists in the avoidance of heat in his preparation.

Landmann's tuberkulol[56] is an extract of tubercle bacilli from virulent cultures, from which the bacilli are filtered out and extracted with water, normal salt solution and dilute glycerin at 40° C.; the fluid is then decanted and the process repeated at successive higher temperatures of 50° C., 60° C., and so on until 100° C. are reached, when the various extractives are put together and concentrated in a vacuum at 37.2° C. and filtered through porcelain. By this method Landmann believes to have extracted all the specific toxins, for which he claims artificial immunity in animals, and good therapeutic results.

Béraneck[57] introduced a new tuberculin in 1903, which consists of the culture fluid plus the addition of toxins extracted from the bodies of tubercle bacilli. He showed prolongation of life for from one to five months in guinea pigs treated with this preparation; and 60 per cent. of his patients improved, though the majority were in an advanced stage of phthisis.

Terre[58] made a tuberculin from cultures of fish tubercle bacilli which he found less effective than the old tuberculin of Koch, and Sciallero[59] made an oleous extract from tubercle bacilli, with which he experimented on animals, and believed it to have some toxic and immunizing powers.

Of interest as regards the fatty extractives contained in tubercle bacilli is the work of Auclair[60] with ether and chloroform extracts. He claims that the ether extractive causes exudative inflammation in rabbits, which is followed by caseation, whereas the substances extracted with chloroform cause tissue proliferation and eventually fibrosis. Armand-Delille[61] also experimented with these extractives, claiming to have produced pachymeningitis and paraplegia in dogs.

Kressling,[62] who further experimented with tuberculin, found it to diminish the virulence of tubercle bacilli in the organism. Pearson and Gilliland obtained partial immunity in the treatment of tuberculous cows, and Jacob[63] likewise experimented upon cows by injecting tuberculin intratracheally and found evidence of curative action by autopsies. Both of these authors fell short of the results reported by de Schweinitz in 1896, who obtained an actual cure in two cows that received very large doses (one to the total amount of three liters), which were well borne and caused no injurious effect.

While I should be glad to refer to other equally interesting and important invertigations on the subject of immunity in tuberculosis which have appeared since 1897, for want of space I am obliged to omit them in order to reach the consideration of Prof. von Behring's latest communication to the International Congress for Tuberculosis recently held in Paris, and to finally state the clinical results and observations from my own preparation.

Prof. von Behring in his communication to the congress claims to have discovered a method of immunization of man which is certain, rapid and free from danger. He has found that the immunizing, curative substance of the tubercle bacilli is contained in their bodies, and this substance he calls "T. C." It is the same substance which produces immunity in cattle by the application of his bovovaccine and acts by combining with certain living cellular elements.

The T. C. is, however, not directly available from unprepared tubercle bacilli as they exist in bovovaccine and in its use in cattle the animal

organism must first free the immunizing substance by removing from the bacilli certain "accidental" and hindering substances, before it (T. C.) becomes available. This liberation of T. C. by the living organism Behring considers both tedious and dangerous, and to save the human organism this tedious and dangerous process he has devised a method of first preparing the tubercle bacilli outside of the body, by which the accidental and hindering substances are removed.

The latter substances are, according to Behring, composed of three groups, one soluble in water, another soluble in a neutral salt solution (10 per cent. solution of chloride of sodium), and a third soluble in alcohol and ether.

When the tubercle bacilli are freed from these hindering groups of substances by their successive extraction with their respective solvents, there remains a bacillary remnant which when mechanically reduced to an amorphous or impalpable powder and injected subcutaneously, induces immunity, as above set forth.

All this, Prof. von Behring has abundantly proved in his laboratory *in vitro* and by animal experimentation, and he is confident that the preparation will protect the human subject against tuberculous infection. For the present the remedy is to be withheld, for purposes of its further experimental and clinical study, except from certain savants to whom only he will entrust it.

Referring the reader now to my own work, and the preparation of tubercle bacilli for the liberation of their specific toxin as published by me in 1897, it will appear that both the theory and method of von Behring show a remarkable coincidence with my own.

In the light of the experience that I have acquired and communicated, I have no hesitation in agreeing with Prof. von Behring perfectly that the removal of the substances of which he speaks, and especially of the fatty wax-like substances, from tubercle bacilli will make the immunizing substance available to a greater degree than it could be were the powdered bacilli injected in an unprepared state.

If, as Prof. von Behring states, he has proved this *in vitro*, he has most probably also extracted his T. C. from the prepared bacilli as I did myself in 1896, and if, as I have shown, the immunizing substance (von Behring's T. C.) can be obtained in its pure form in solution there are several good clinical reasons why the injection of the bacillary residue, which contains it, should be avoided. These reasons are:

First, that although made available, the organism has still to extract the desired substance from the prepared bacilli, and there being no definite knowledge how much will be extracted, or how long it will take for a certain quantity to become absorbed, as this process may vary in quantity and time and with the individual to be immunized, there is an uncertainty in dosage and the possibility of cumulative effects.

Second, that there can be no absolute guarantee that all the hindering substances have been completely removed, which is especially difficult with regard to the fats, and may on that account lead to variability in the preparation.

Third, that even the completely extracted bacillary residue can still give rise to tubercle formation in the tissues, and although not liable to degeneration and caseation, as are infectious tubercles, such tubercles would by no means be indifferent in effect should they, perchance, form in the brain and spinal cord or their membranes, or in the tunics of the eye, parenchyma of the kidneys, etc. The formation of such tubercles at the point of injection in the subcutaneous tissue would, of course, be indifferent, but in practice we have to consider the possibility of unintentionally puncturing a vein, and of accidentally discharging the amorphous bacillary residue into the general circulation.

Comparing now the method of removal of the substances which hinder the liberation of the immunizing curative toxin (the T. C. of von Behring), with the method followed by me, it will be seen that von Behring introduces a second step, not mentioned in my publication, namely, the extraction with a solution of chloride of sodium.

If the substance extracted by this solution were not soluble in water it could not enter into my preparation, for I extract only the substances soluble in water, as a first step, and the fats thereafter.

I have, however, found that the chloride of sodium extractive is likewise soluble in water, only much less so, and when I have since resorted to the salt solution it has been to save time in the tedious preliminary washing upon a filter or precolator. When after extraction with salt the latter is removed from the solution by dialyzing through an animal membrane and the fluid is concentrated, there is no precipitation of the organic substance it contains, and the physiological action is that of tuberculin in nowise distinguishable from that of substances extracted with water alone and without the aid of a neutral salt. Furthermore, the substances extracted with water alone, and the substance extracted with salt solution appear to give the same chemical reaction, and when the water extraction is carried far enough, a salt solution extracts nothing more.

I hold, therefore, that the extraction with a salt solution is a matter of laboratory expediency only, and not essential in any way to the liberation of the immunizing substance.

I have also reason to believe that the substance removed by water (excepting the ingredients of the culture fluid) and that which is removed by a solution of chloride of sodium have the same origin in a secretion product of the tubercle bacillus. This substance has been called a mucoprotein; it forms and is deposited upon the exterior of tubercle bacilli and causes their adhesion in mass; some of it is dissolved in the culture fluid during the growth of the culture, while some of it is in a state of incomplete solution still adhering to the tubercle bacilli when they are removed from the culture; this part is, therefore, more quickly removed by the first water extraction while the rest goes into watery solution more slowly, and the presence of chloride of sodium hastens its removal.

This mucoprotein is probably the same substance which von Behring seems to have extracted on a former occasion, and which he described in his communication to the Congress on Hygiene and Demography in 1898. Landmann also appears to have extracted it with water, normal salt solution, and glycerin and called it tuberkulol; and Maragliano's watery extract of tubercle bacilli contains mainly the same substance. The extractive with water with or without the presence of a neutral salt is also a specific toxin of tubercle bacilli. From my studies of this substance in its pure form I am by no means prepared to agree with Prof. von Behring that it is an accidental one, or one necessarily hindering the action of the substance which he calls T. C. At all events I have already attained some interesting data by experimentation, and hope that by continuing my studies this toxin will also be found

to have a value in immunization or for certain indications in the actual treatment of tuberculosis.

I believe I have made it sufficiently evident in the preceding pages that if Prof. von Behring's statements before the Congress on Tuberculosis are correct, his discovery, if he has made one, consists in the liberation of the immunizing curative substance which he calls T. C. by the removal of other substances which hinder or prevent this liberation, and that in this respect I have preceded him by a period of over eight years.

The method of preparation followed, as well as the experimental and clinical data published by me can leave no doubt of the fact that my preparation contains the immunizing substance to which Prof. von Behring refers. As additional evidence I may here mention the fact, that under its clinical use specific agglutinins are developed and form in the blood serum of patients, and that these agglutinins increase in amount under its administration.

A study of the bactericidal action of blood serum from man and animals prior to their immunization, and again at periods cerresponding with certain degrees of agglutinating power reached, has been in progress in my laboratory for some time, and when concluded will be duly published.

As to the method of the therapeutic procedure, *i. e.* immunization with the prepared powdered bacilli, or with the solution of the specific toxin which I have followed, I believe my method will not suffer by comparison in the clinical test, with which I have had a long experience and which has met all the expectations that one can reasonably entertain, not only in my own hands, but also in the hands of many other physicians. Some of these have reported to me directly, while others have heretofore published their observations and their results.

For publications and discussions by others on the value of my method I refer the reader to Williams,[64] Sutherland, [65] Baker, [66] Denison, [67] McMaster,[68] Weaver,[69] Durel,[70] Matas,[71] Parham,[72] Pottenger,[73] Briggs,[74] High,[75] and Sawyer,[76] who bear me out in my every claim I have heretofore made and confirm my own results heretofore made public.[77]

For a correct estimate of the value of any specific remedy, we should consider only cases in which the disease exists in an uncomplicated form, and in which it is still in a stage where entire restoration is at least theoretically possible.

If we take therefore only cases in the early stages of tuberculosis, and of beginning phthisis, my bi-annual reports of cases of pulmonary tuberculosis treated at the Winyah Sanitarium show the following results:

	Cases Treated.	Re-covered.	Per cent.
Report of 1899.....	20	20	= 100
" 1901.....	53	49	= 92.5
" 1903.....	53	48	= 90.6
" 1905.....	45	44	= 97.8
	171	161	94.2

This shows for this class a recovery in 161 out of 171 cases, or 94.2 per cent. The other ten cases, which were all improved, left the institution either satisfied that they had attained all they wished, or to continue the treatment at home.

But even in more advanced cases it has been found that immunization is of great value, and that a large percentage can attain a lasting arrestment of, and practically a recovery from, their phthisical processes.

In this class the results were as follows:

	Cases Treated.	Re-covered.	Per cent.
Report of 1899.....	37	27	= 73
" 1901.....	80	51	= 63.8
" 1903.....	139	73	= 52.5
" 1905.....	94	79	= 84
	350	230	65.7

It will thus be seen that two-thirds of all this class still made a recovery, while the report shows that in all but a very few, more or less decided improvement occurred before the patients left the institution.

If we finally consider the cases still further advanced in consumption the results still justify the trials made.

	Cases Treated.	Re-covered.	Per cent.
Report of 1899.....	21	3	= 14.3
" 1901.....	92	20	= 21.7
" 1903.....	117	41	= 35.
" 1905.....	122	32	= 26.1
	352	96	27.3

A still larger number of patients of this class were greatly improved. We have therefore in the far advanced stages still 27.3 per cent. of good results, a ratio which exceeds that obtainable without immunization even for the most favorable class of tuberculous patients.

Concerning the duration of these results after discharge, an inquiry which had been carried on for the last year is still incomplete, but from reports of over 80 per cent. of the patients whose condition has thus far been ascetained, either directly or through their physicians, or again by examination by myself, including a tuberculin test, I can already say that there have been but very few relapses in the cases reported as recovered, and that the number of permanently recovered cases will not appear materially diminished when the inquiry is complete and ready for publication.

The reports referred to above give additional information to the interested student, more particularly by showing also the results in tuberculosis of other parts and organs, especially of the larynx.

I wish now to refer to the work of Prof. von Behring but once more, in order to say that I sincerely hope that when his completed work has been published and when the clinical trials have been made it will appear that he has, after all, advanced the subject of specific treatment of human tuberculosis, and has devised an additional improvement in a method of treatment, for which the first credit must ever belong to Prof. Koch, who is its real discoverer. Those who have followed after him have made but improvements, more or less important, and all that I wish to secure for myself is the recognition of what little I may have contributed toward the progress of the work.

A study of all the various preparations, beginning with old tuberculin, can leave no doubt that most, if not all of them, contained more or less tubercle bacillus toxins, and that, corresponding with the form of this toxin and with the amount contained, and with the absence of admixtures and impurities from external sources or from inert substances of the tubercle bacilli themselves, and according to the avoidance of injurious methods of preparation (chemicals and high degrees of heat), the various tuberculins heretofore introduced showed more or less evidence of value.

The statement made by von Behring at the Con-

gress on Tuberculosis, that until now all the specific remedies introduced have yielded valuable results only in the hands of their authors, is certainly unjustified. On the contrary, and without considering the claims of others, Prof. von Behring owes a better acknowledgment than this to Prof. Koch, especially with reference to the preparation of bovovaccine, which consists of dried-powdered living tubercle bacilli of human origin, which are not infectious for cattle. Inasmuch as Koch's tuberculin R. consists also of finely powdered living tubercle bacilli of human origin, and was introduced long before von Behring introduced his bovovaccine, I cannot well see that von Behring made a new discovery in the preparation, or that his merit can be looked for elsewhere than in the application and exploitation of Koch's labors for the industrial protection of cattle.

Neither von Behring nor I can claim a new discovery of a remedy for human tuberculosis. In the evolution of the labors for perfection of Prof. Koch's work, many other men have contributed directly and indirectly and they are all co-workers in a common purpose and cause that is of the utmost importance, and in the contemplation of which a dispute over claims of precedence is comparatively insignificant.

In the meanwhile it is proper that von Behring's method should have a careful and impartial trial, and if it is correctly stated, there is no difficulty in giving it an immediate one by animal experiments at least, even if von Behring declines to supply the preparation. Any competent bacteriologist can readily produce it himself, and I am myself able to place at the command of those who wish to experiment, the necessary quantities of tubercle bacilli extracted and prepared identically with von Behring's published method, and in a state which I necessarily reach in my own preparation, prior to the final extraction with distilled water.

In conclusion I may venture to express my belief in the approaching realization of Prof. Tyson's prediction,[78] made in 1884, when, in a clinical lecture on pulmonary phthisis, he said: "Consumption is a specific inflammation. Some day we may discover a specific remedy for the specific inflammation of consumption, a remedy which will give us the same power over this disease which we now possess over syphilis."

A FEW FACTS CONCERNING CANCER OF THE STOMACH.*

By CHARLES N. DOWD, M.D.,

NEW YORK.

Your President, in arranging for a series of short papers on certain abdominal disturbances, which are of common interest to physician and surgeon, has begun with the stomach, partly, no doubt, because digestive discomforts begin here, but more, perhaps, because there is less accord here than in many other organs as to what should be considered medical and what surgical cases.

The peculiar difficulties in diagnosis explain this lack of accord. The stomach is so situated that palpation is not satisfactory. The border of the ribs protects it so that a mass of considerable size may exist which cannot be felt; and if one waits until the palpable mass exists before making the diagnosis, the growth will have often progressed beyond the favorable stage for treatment.

The most important surgical ailments of the stomach are cancer and ulcer. The ulcer surely has as much surgical importance as the cancer; from the pyloric stenosis which may follow its healing; from the digestive disturbance which may accompany its presence when not healed; from the hemorrhages which sometimes occur; and from perforation which may result in general peritonitis, or in local peritonitis with consequent symptoms. It is difficult, however, even to touch on the important facts about gastric cancer in the time allotted for this paper, and hence I will ask your forbearance and postpone the consideration of the ulcer which was announced on the program.

Without attempting to consider the entire subject of gastric cancer, Iwill ask your attention to four topics concerning it: (1) The frequency of its occurrence; (2) its position as a surgical disease;(3) the customary method of treatment in our city; (4) the possibility of making a diagnosis in the early stages of the disease.

Perhaps the most startling fact concerning gastric cancer is the frequency of its occurrence.

The United States census report for 1900[1] indicates that there were at least 9,000 deaths from cancer of the stomach in the country in that year. In the registration area there were 4,220; this is 65 per cent. more than from appendicitis and materially more than from scarlet fever, measles, or whooping-cough.

A table which gives the records of the registration districts indicates that 31 per cent. of the fatal cancers whose location was recorded were gastric; 16 per cent. were uterine; 13 per cent. were hepatic; 10 per cent. were mammary; 8 per cent. were abdominal; 6 per cent. were of head, neck, or face; and 5 per cent. were of the mouth, tongue, and throat.

*One of the papers read before the New York County Medical Society, December 26, 1905, on "Digestive Disorders and Abdominal Pain from the Standpoint of the Surgeon."

As a matter of fact this estimated frequency of gastric cancer is probably much too small, since it is altogether probable that a part of the cases recorded as located in liver and abdomen were really primarily gastric. It is also probable that many of the 13,484 deaths ascribed to "gastritis," and "diseases of the stomach," were also cancerous.

Statistics indicate that there is a steady increase in the proportion of the population afflicted with cancer, and also that stomach cancers are increasing more rapidly than those located elsewhere. From 1890 to 1900 the ratio of cancer deaths per 1,000 of the total deaths increased from 22 to 28. In 1880 the ratio of breast, uterine, and stomach cancers stood 10, 14, 20, while in 1900 it stood 10, 16, 31.

The vital statistics of our city indicate that conditions here correspond to those in the country at large. The Registrar's report for 1903 shows that in thirty years the death rate from cancer increased from 423 to 642 per million of the population, and that in that period cancer of the stomach, liver, and intestines increased from 40 per cent. to 53 per cent. of the entire cancer mortality, and that mammary and uterine cancer decreased respectively from 13 to 9 per cent., and from 28 to 16.4 per cent.

The *second topic* to which I would ask your attention is generally accepted in theory and rejected in practice. It is that cancer of the stomach is primarily a surgical disease. We know of no internal treatment which is ever curative, but there is a fair proportion of patients who have lived in good health many years after operation. The mortality rate for the operation is no higher than that for many other operations which are more frequently done. Mayo,[2] Kocher,[3] and von Eiselberg[4] report long series of gastric resections or pylorectomies with mortality rates of respectively 14.5, 16.9, 18.7 per cent., and there are at least three series of 25 to 35 cases with a mortality rate of only 4 to 8 per cent.

The details of the technique of this operation have been simplified and perfected by many operators, but particularly by our own countryman, Mayo, who considers it no more difficult than a hysterectomy, and it is now fair to state that with cases fairly well selected the present mortality rate is about 10 per cent.

The permanent results of these operations are also encouraging: Eleven of Mayo's 81 cases were too recent to be of statistical value at the time of his report; 5 failed to live six months; 38 lived six months to a year; 21 lived one to two years; 10 lived two to three years; 4 lived three to four years. Only 16 of the cases were operated upon more than three years ago, hence 25 per cent. of them lived three years, one of whom is alive and well after four years and ten months.

Kocher's statistics refer to 71 patient on whom he had successfully done gastric resection or pylorectomy by various methods for carcinoma. 28.2 per cent. of these patients were living at the time of the report, one of them sixteen and one-quarter years after operation. The average lapse of time since the operation for these 20 living cases was three and three-quarters years; 71.8 per cent. had died from one month to six years after the operation, the average duration of life being a year and a half. We might quote statistics from many of the large European clinics, but these are sufficient for illustration.

A patient, who is here shown, and who has come from the country to be at this meeting,

is an illustration of the good results which may come from the surgical treatment of this condition. He is a man of 54, who is now in good health and working regularly about his farm; he had a pylorectomy for adenocarcinoma August 6, 1902. He had since boyhood suffered from digestive disturbance, with flatulence, pyrosis, and occasional vomiting. For six months or more before operation these symptoms became more marked, and progressive loss of weight and strength was added to them. Dr. George L. Hubbell, of Hobart, N. Y., made the diagnosis of gastric cancer, although no mass could be palpated in the epigastrium. Before operation was done his weakness progressed so as to be alarming. He could, for instance, hardly carry anything from his house to his barn, and when he came to the city and walked up the steps of a house, his dyspnea was so distressing that he looked like a man with a serious cardiac lesion. None was found, however, and after a few days' rest in the hospital, an exploration was done and a large adenocarcinoma was found projecting into the stomach cavity from the posterior wall of the pyloric end of the stomach.

This end of the stomach was, therefore, excised and he made a rapid recovery, left the hospital on the twenty-sixth day, promptly gained 25 pounds in weight, and has been enjoying good health and working as a farmer ever since, a period of three and a half years.

In November of this year the writer showed a similar case to the New York Surgical Society, a young woman, about half of whose stomach he removed in June of this year. She is now in better helath than she has ever known before, has been to Europe in the meantime, and is attending to her ordinary duties. These two cases surely justify much work on the subject; among the writer's list of thirteen operations for carcinoma of the stomach they are the best. Four others, however, were much benefited by gastroenterostomies. In three only exploratory incisions were made. The remaining four, who had very extensive growths, died within a month. The results corresponded to the pathological condition found. Those with circumscribed growths were greatly benefited; those with more diffuse growths were somewhat benefited; those with extensive growths were not benefited.

The *third topic* concerning gastric cancer to which your attention is called is perhaps of local rather than general interest; it relates to the number of gastric cancers in our city which really receive surgical treatment. This number is relatively very small indeed. Cancer of the stomach was given to the Health Department as the cause of death in 1,141 cases last year in Greater New York. A search of the reports and records of 25 of our hospitals for that year indicates that only 98 operations were done in them for that disease. These hospitals treated a total of 89,353 patients in their wards, and comprise all of the general hospitals of which the writer could get records.

Of course some operations for gastric cancer were done outside of these hospitals, and again there is a liability to error in the interpretation of the hospital records, but the ratio of 98 to 1,141 is as 1 to $11\frac{3}{4}$, and making any allowances for error which one may wish, the evidence is overwhelming that the surgical treatment of cancer of the stomach in our city is the exception and not the rule.

The records of the General Memorial Hospital in this city indicate the same thing. As stated before, vital statistics indicate about three stomach cancers to one breast cancer, and about two stomach cancers to one uterine cancer. Yet, in that institution, there have been admitted since its foundation in 1888, 1,018 uterine cancers, 888 breast cancers, and only 72 stomach cancers, and of these 72 only 38 were deemed suitable for even an exploratory operation.

The *fourth topic* concerning gastric cancer relates to the possibility of making a diagnosis while there is still a fair prospect of cure. When the growth is circumscribed and gives early pyloric obstruction, and possibly a palpable tumor, this diagnosis should be made in a large proportion of cases. When, however, there is a diffuse cancerous involvement of the stomach walls, an early diagnosis is not likely to be made. The patient who has the symptoms in an exaggerated form will have severe attacks of vomiting, usually not long after eating. A portion of the vomitus may resemble coffee-grounds. There will also be severe attacks of pain coming at about the same time; in fact, patients sometimes bring on artificial emesis to relieve the pain. Loss of strength and weight will supervene, and a mass will be felt in the epigastrium. Unfortunately the symptoms do not often come in this tell-tale way. Kocher found that the initial symptoms of diminished appetite, pyrosis, and epigastric discomfort often precede the severe vomiting by many months, and that this severe vomiting, which he considers the most important symptom, is not constant. He found it in 73 per cent. of his cases, having existed on an average about seven months before admission to the hospital. It came sometimes after each meal, sometimes daily, sometimes at irregular intervals, in rare instances where great dilatation existed food coming up which had been swallowed days before.

Pain, although less characteristic than the vomiting, is still an important symptom; it is often associated with gastric adhesions. The relief which comes with emesis is apparently due to the quiet which the stomach then has.

Loss of weight and strength eventually comes to all these patients, but not always in time to lead to an early diagnosis.

The presence of a palpable mass is, of course, a most important diagnostic aid, and skill is developed in this palpation, as in other abdominal examinations. Kocher records a palpable tumor in 73.3 per cent. of his cases, and a feeling of resistance in 8.2 per cent. more. Matti[3] quotes Nordmann, Kappeler, and Kronlein as having felt epigastric tumors in, respectively, 89, 96, and 91 per cent. of their cases. In many cases the growth passes by the stage favorable for operation before it is palpable in the epigastrium, but in some instances a nodular, movable growth similar to the second of the writer's cases referred to above may be distinctly palpated while still in the favorable stage for removal.

The chemical examination of the gastric contents is helpful, but may be misleading. The different examinations from the same stomach may differ much, and although absence of hydrochloric and presence of lactic acid may indicate cancer, it does not surely do so; and on the other hand hydrochloric acid may be present and lactic acid absent in a stomach which is the site of cancer.

Exploratory operation has a distinct position in making the diagnosis of this condition.

A small incision of one and a half or two inches between the umbilicus and ensiform cartilage is sufficient for introducing the finger, and is often sufficient to establish the diagnosis; it can be enlarged if further operation or examination is needed. Mayo has his patients out of bed two or three days after such an exploration. Deaver[5] considers an exploration less objectionable in this than in any other class of cases.

Many able medical men are devoting much study to this condition, not only by clinical and laboratory methods, but by attending the operations on their cases and witnessing the conditions *in vivo*; and it is fair to believe that we shall see the same development in diagnosis in these cases which we have seen in other abdominal conditions. Most of us can remember when the diagnosis of appendicitis was usually made on the appearance of a large abscess; the diagnosis of ectopic gestation after a fatal hemorrhage; intussusception, volvulus, and intestinal perforation after the onset of general peritonitis; cholecystitis when abscess formation had occurred; yet in all these conditions a skill in diagnosis has been developed commensurate with the gravity of the conditions, and a similar increase in the ability to deal with gastric cancer may be expected.

DIGESTIVE DISORDERS AND ABDOMINAL PAIN.

FROM THE STANDPOINT OF THE SURGEON AS TO GALL-BLADDER, PANCREAS, AND GASTRIC ADHESIONS.*

By JOHN F. ERDMANN, M.D.,
NEW YORK.
VISITING SURGEON TO GOUVERNEUR AND SYDENHAM HOSPITALS.

The field assigned to me for consideration is comprised in an area irregularly pyramidal in shape, the base not exceeding three inches square in the normal human subject, with the apex made by the common biliary duct, head of the pancreas, the duodenal end of the stomach, and the first portion of the duodenum; while in the base, during health, we have the fundus of the gall-bladder, a portion of the lesser curvature of the stomach, etc.

The difficulty of clinically establishing an absolute diagnosis of disease invading one of the structures mentioned as forming the apex of the pyramid, can readily be understood, and therefore it is manifestly important that all aids in the chemistry of digestion and the excreta, be called into play. Unfortunately, from a clinical standpoint, chemistry has not reached that degree of perfection one could wish for when a definite or absolute diagnosis is demanded.

We, as operators, are frequently disheartened by the evidences of new growths presented upon exploration, when the chemical analyses, as at present understood, have pointed to an entirely different condition. As a result of these conflicting chemical conditions, symptomatology must, for the present, be relied upon by us, in urging the patients to accept an abdominal section, which may smatter somewhat of an exploration. But far better be it that such an exploratory examination be made, with its findings, than to wait for a pronounced motorial insufficiency or tumor presence.

*Read before the Medical Society of the County of New York, Tuesday, December 26, 1905.

Digestive Disorders.—Under this term I shall consider, in a differential sense, only the proper transit of food through the gastrointestinal tract, with its proper disintegration for absorption, its fermentation or flatulence production, and finally its exit as effete matter. Transit through the gastrointestinal tract is modified by new growths, diminishing the intestinal lumen either from within or without, and by gastric adhesions. In the latter it is due in all probability, to the adhesions either kinking the pyloric orifice, so as to act mildly as an obstruction, or by producing a gastroptosis, or finally by so involving the musculature of the stomach, as to prevent proper muscular contractions. While in the former condition, whether due to exudate, pus, blood, or new growths, the cause is in the nature of a compression, or internal occlusion of some portion of the stomach or bowel in this pyramidal space.

As a result of motor insufficiency or obstruction, all the symptoms of a pyloric stenosis with its subsequent pathological conditions, may be present. The proper disintegration of food is not markedly modified in the earlier gastric adhesion cases, and a sense of epigastric weight may be elicited. Flatulence is not marked, nor is there ordinarily any evidence of any undigested food in the excreta.

In gall-bladder invasions, owing to increase in size from whatever cause, there may be obstruction by pressure on the duodenum. There is always a history of flatulence and sense of weight in the epigastrium, and occasionally partially digested food contents, and some fat in the stools in addition to those modifications of the excreta due to the absence of bile, especially found in invasions of the common biliary duct.

In pancreatic disease not including malignancy, we are prone to have a gall-bladder or duct history, or a history of sudden onset of pain with subsequent tumor formation, and its pressure symptoms or early demise by a rapid fat necrosis and toxemia, following the onset of pain. In interstitial pancreatitis, more or less flatulence is manifested. The close association of this type with gall-bladder or duct disease, may be accountable for the latter condition. The excreta contain in many instances, globules of fat, and partially digested muscle fiber. It has been observed that liquid fat is expelled after a normal stool, and also that the stools may be much larger than normal, when compared to the amount of food taken.

In addition, as a differential factor in the diseases of these three viscera, the analysis of urine must be taken into consideration. Sugar in the urine has been claimed as a factor in pancreatitis. I have had four cases, in none of which sugar was present at any stage.

Dr. Wm. S. Thayer reports five cases of pancreatitis in the Johns Hopkins Bulletin for November, 1905, in none of which sugar ever appeared at any time, while under his observation. With these nine unselected and consecutive cases, with no sugar in any of them, one is led to question its weight when present.

The presence of lipase in the urine was shown by Hewlett (see Thayer's article) to be a constant factor in all cases of insult to the pancreas,

but to obtain this reaction requires a complex process and a period of over twenty hours of actual preparation. During such a period of time one would lose a brilliant opportunity, in many a case, of saving a life.

Pain.—No pain of any moment is evidenced in the gastric adhesion cases; the patient's only complaint in this regard is a sense of soreness or distension. In gall-bladder disease, the pain varies from practically none, to a pronounced attack of colic requiring large doses of morphia. In the non-inflamed cases, a sense of soreness is described as seated behind the ninth or tenth costal cartilage on the right side, and can always be intensified by digital pressure close to the arch in this region, while in duct stone the pain is deeper seated, and the pressure must assume a more oblique direction, pointing nearer the median line. Pain also in these cases is evidenced in the back, radiating from the right to the left side, also upward to the right or between both shoulder blades.

In pancreatitis of the chronic variety, the pain is of a dull character to a back-splitting type, and is usually assigned to the dorsilumbar region; while in the acute variety the pain is as a rule more intense than in the passage of a biliary calculus, and may be generalized as in acute appendicitis, or as in one case recently seen by me, in which after the subsidence of shock, markedly intense pain was felt, after three-quarters grain of morphine had been given in six hours, only in the left iliac fossa; this may have been due to the free beef broth like fluid in the pelvis, or to the reflection in the sympathetic plexus; while in the second case pain was evident after the first six or eight hours, only in the region of the ninth and tenth costal cartilages of the left side.

Case I.—Gastroduodenal and biliary adhesions, with gastroptosis. A woman thirty-five years old was seen by me on July 3, 1905. Family history negative; operation for appendicitis and ovaritis eight years ago. Following the operation, although she stated that she had had a "catarrh" of the stomach for eight or nine years, she felt perfectly well. In September, 1904, while in the mountains, as a result of taking an excess of spring water, an attack of diarrhea was induced, accompanied by a temperature of 104° to 105°, which lasted for five days. From this time to January, 1905, she has been unable to retain food, claiming that it produced pain and nausea; at the same time admitting no time relationship between the intake of food, and its pain and nausea production. This condition subsided, so that from January to June, 1905, she felt fairly well.

From June to the time I saw her she was again complaining of her former symptoms of nausea, vomiting, and pain. The vomiting, while occurring four or five times a week, was never cumulative, but always the last meal ingested. There is also some pain in the right axillary line below the costal margin upon deep inspiration. She assumes the stooping rather than the erect posture when sitting, claiming less nausea and pain by this position. Pain after food is not in the epigastrium, but rather high and toward the median limit of the right hypochondrium. Has had to resort to morphia on several occasions. Loss of weight, twenty pounds at present, although it has at one time been as much as thirty-two pounds. Constipated; never jaundiced to her knowledge; appetite good; weighs one hundred and eleven pounds.

Examination revealed a painful gall-bladder region, and a right movable kidney. A diagnosis was made of adhesions or gallstones and movable kidney, and I advised exploration. This diagnosis was surprising to her and her husband, a physician, who stated that she had been under the care of the best stomach specialist, and as a result of repeated tests, ulcer and gastralgia were the invariable diagnoses.

August 28, kidney somewhat more displaced, nausea and vomiting increased; now weighed one hundred and nine pounds and was becoming exhausted. Operation again advised, and she was then seen by Dr. Adler, who also advised exploration. Operation was done on September 19. Right rectus incision. The gall-bladder had two small bands leading to the duodenum, between the first portion of the duodenum and the lesser curvature of the stomach, a filmy but firm band about two inches wide was distinctly demonstrated and a marked angulated gastroptosis evident. The gall-bladder contained no stones. The adhesions were removed; three chromic catgut stitches were used to anchor the lesser omentum to the parietal peritoneum, thereby elevating and correcting the angulated gastroptosis. No vomiting or nausea has followed, all foods are being taken with a relish, and up to to-day a steady increase in weight has taken place.

Case II.—Acute Hemorrhagic Pancreatitis. Miss D., age thirty-two, was taken with a most excruciating pain in the abdomen while at mass, at eleven o'clock on Sunday morning, October 8, of this year. The pain was so severe that she fell, although she retained consciousness. Upon arrival at home about noon, she was seen by Dr. Hadden to whom I am indebted for the case, who gave her a quarter grain of morphine, followed it in two hours with another quarter grain, and again in two hours with another equal dose. I saw her at 7:30 P.M. and found a rigid abdomen and pain only in the left iliac region. Her pulse was 98, and the temperature 100°. There was a peculiar livid, and a most anxious appearance and anxious mentality. Immediate operation was advised. She was operated upon about eleven hours after the onset of pain, through a Kammerer incision. The abdomen contained a large quantity of beef-brothlike bloody serum. The appendix was not acutely involved, but the inflammation was a chronic one, characterized by a central distention and by a distal and proximal atrophy. The appendix was removed and the incision was continued upward after I had satisfied myself that the pelvic contents were normal. Upon pulling down upon the stomach and duodenum, the pancreas was readily seen under its peritoneal layer as large as a fair sized fist and of a blue-black color. The peritoneum over the pancreas was incised, a blunt instrument passed into the pancreas, and a large cigarette drain and additional gauze packing introduced; and after a large piece of rubber tissue had been used as a dam to exclude as much of the contents as possible from the general cavity, the abdomen was sutured up to the drain. There was a profuse discharge with a musty odor, and of the same color as the fluid found at the time of the operation, but with an additional mucilaginous feel, which continued for six or eight days, it being necessary to change large abdominal dressing pads four to eight times a day. During the first five to seven days it was observed that areas of fat necrosis would appear on the sub-

cutaneous fat in the drainage gap. Pain of a splitting character in the back was a feature from the first day until the third week. No sloughs were discharged, the drain sinus persisting until the latter part of November. No sugar was ever found in the urine, and no digestive disturbances were noted during the entire convalescence.

Case III.—Gallstones in the common duct; repeated attacks of jaundice; no colic at any time. This patient was referred to me by Dr. Conrad of Hackensack, on November 22, 1905. The patient was a woman, forty-six years old, married. The father died of biliary (?) fever. Up to February of this year, barring occasional attacks of abdominal distention, she was perfectly well. At that time she weighed one hundred and ninety-two pounds; thirty days ago she weighed one hundred and sixty pounds. In February, 1905, she had an attack of "distress" in the stomach; no pain; loss of appetite; chill for four hours; feverish; slightly jaundiced before the chill; profoundly jaundiced after the chill; unbearable itching; white stools; yellow urine. Following this attack, she had from one to eight attacks a month, of varying intensity as to jaundice, and lasting from one to several days. Certain foods, particularly greasy ones, would seem to bear some relation to an attack. Vomited occasionally. Now weighs one hundred and fifty-nine and a half pounds, with extra heavy winter clothes on.

Examination showed the patient jaundiced and emaciated. Physical examination, except that of the duct region, negative. Pain on pressure over the region of the common duct.

Operation, December 4. Exposure of the gall-bladder region brought a mass of adhesions into view, with no distinguishable gall-bladder. The liver at the usual site of the gall-bladder was sclerotic and mottled gray over an area of about two and half square inches. A large hard mass two inches long by one and a half inches wide, filling what appeared to be a portion of the duodenum, was brought into the wound after liberating the adhesions. This proved to be a stone one and a half inches by one inch in the common duct, at the posterior surface of the duodenum. The gall-bladder was completely atrophied. Stones were also found in the hepatic ducts, and another large stone the size of a filbert in the common duct, in contact with the first.

Choledochotomy was done, the hepatic ducts were relieved of three stones and the abdomen was closed. The patient has made a perfect recovery. Why this patient never had any colic is hard to explain. Her vomiting could readily be explained by the narrowing of the duodenal lumen by angulation of the duodenum over the stone and posterior pressure, thereby inducing a temporary or transitory pyloric, or duodenal stenosis, varying from partial to complete in degree.

60 West Fifty-second Street.

Sincere Quackery.—The following rather remarkable case of honest but fanatic belief in the therapeutic efficacy of a medicinal compound, which occurred in London some time ago, is related in the *Globe*. An old lady sued Sir William Broadbent, a leading London practitioner, because he refused to buy or try her elixir. This "was no common remedy, being free from those minerals which are the root of all evil, but the skilful blending of a herb of which medical men know nothing." Needless to say the old lady lost her case, which she pleaded in person. Her sincerity was as obvious as her stupidity and made her a pathetic rather than a ridiculous figure.

THE DISTRIBUTION OF MOSQUITOS IN THE UNITED STATES.*

AS SHOWN BY COLLECTIONS MADE AT ARMY POSTS, 1904-1905.

By C. S. LUDLOW, M.Sc.,

WASHINGTON, D. C.

Under the authority of the Surgeon-General, U. S. Army, collections of mosquitos have been made during parts of 1904 and 1905 for the purpose of determining what mosquitos were present at the various Army posts. The first collections were restricted to the Southern States, but in 1905 all the stations in the United States were included in the work. However, owing to the facts that the collections did not begin until late June this year, and at some of the Posts only one, or no collection was made, the list is still quite imperfect, though points of much interest alike to medical and entomological workers have been brought out.

In considering the following list it is necessary to remember that a given mosquito is not necessarily absent from a Post because not reported, for the Anophelina especially are relatively shy and often escape the collector. A good example of the foregoing is the condition at Fort Hamilton, N.Y. Harbor, where, during a malarial outbreak in the summer of 1904, anopheles were sought for diligently, but none taken till November, when one specimen of *Anopheles punctipennis* Say. was secured; as however, *punctipennis* has so far given only negative results in experiments with the malarial parasite, it could not be held responsible. Collections were resumed July 5, 1905, the report, "a few cases of tertian malarial fever under treatment" being sent with the first collection; but in spite of the careful and painstaking way in which the collections were made, it was August 9 before a single anopheles was taken; then some specimens of *Anopheles maculipennis* Meig. were sent in, and it has appeared occasionally in the collections since. That these mosquitos were present earlier in the season, and also last year, is practically certain, but it took almost daily collections at various hours, for nearly a month to prove their presence.

In regard to *Stegomyia fasciata* Fabr. a word is perhaps wise. Dr. L. O. Howard has shown (Public Health Reports, "Concerning the Geographic Distribution of the Yellow Fever Mosquito") that this insect will breed within the northern limits of the "Lower Austral Zone," and that it may occur for a season beyond this if carried by artificial means (cars, boats, etc.). It is, however, to be borne in mind that while *S. fasciata* may breed in these limits it is not present at some localities where we would naturally expect to find it; two Posts will serve as examples: (*a*) Fort De Soto., Fla., from which as high as 1187 mosquitos of one species were sent in one collection, has never sent one *S. fasciata*, and (*b*) Fort St. Philip, about 70 miles south of New Orleans, in the marshy land on the Mississippi, also well within the Austral limits, has also never, in two years, sent a single specimen, though they were sought for with great care by both Dr. G. W. Daywalt, Cont. Surgeon, U. S. A., and Dr. J. R. Johnson of Empire City, two cases of yellow fever imported from New Orleans which developed fatally in the latter place, only a few miles distant from Fort St. Philip, being the immediate cause of this active search. In passing

* Prepared in December, 1905, and published by authority of the Surgeon-General, U. S. Army.

it may be of interest to add that no other cases occurred at Empire City. There has lately been published a statement that *S. fasciata* bite at night only after being infected; this is open to criticism inasmuch as in the Philippines, where this mosquito abounds, and where no yellow fever is known, it bites freely in lighted rooms, at night, and is often found in the bed nets in the morning in a condition that leaves no room for doubt as to its activity.

The classification used in determining the mosquitos listed in this paper, is that of Mr. F. V. Theobald, M.A., Cantab., British Museum, as published in his Monograph; and the basis of differentiation is, in many cases, largely dependent on scale structure and position, which, of course necessitates microscopic study. The system is not perfect, but so far no one has presented a better one, those offered being open to quite as serious objections as are urged against this. Also, in this paper, no attempt has been made to differentiate species whose larval characteristics were the sole basis for their creation, for these larval differences, while of great philogenetic interest, are of little value to the systematist unless the differences occur also in the adult, as it is with the adult, the perfect, and reproductive form that he must of necessity deal.

The genera are grouped in their sub-families, the localities given alphabetically, and, except in the *Anophelina*, *Stegomyia fasciata*, and *Culex fatigans*, where species have been found in more than one locality in a State, merely the State is given.

Besides the three new species given in the list (which were described within the year) there still remain a couple of very variable forms, apparently new, which have not yet been satisfactorily placed.

OBSERVATIONS ON THE USE OF THE *X*-RAY IN THE TREATMENT OF CERTAIN DISEASES OF THE SKIN.

By FRED WISE, M.D.,

CLINICAL ASSISTANT, AND ASSISTANT RADIOTHERAPCUTIST NEW YORK SKIN AND CANCER HOSPITAL.

At the time an *x*-ray outfit was installed at the New York Skin and Cancer Hospital, radiotherapy, as applied to cutaneous affections, was still in the experimental stage, and probably most of the diseases known to the dermatologist received a goodly share of the would-be universal remedy. At that time it was thought that the *x*-ray would turn out to be a *sine qua non* to every dermatologist in the country. Diseases which had, heretofore, withstood many forms of treatment, as well as those which could be readily cured by medicinal remedies, were recklessly and indiscriminately offered up to the mercies of the *x*-ray. A knowledge of the proper technique in the treatment of lesions of the skin and of its appendages was very meager—perhaps *nil* in the greater number of experimenters. Such a state of affairs was naturally bound to bring about unfavorable results, sooner or later; *x*-ray burns, some of trifling, more often of serious extent, were unpleasantly frequent; lawsuits were heard of from many sides; the profession began to look askance at this latest of remedies; the *x*-ray began to be handled, figuratively and literally, "with gloved hands."

Scores of American and European writers published reports of remarkable, sometimes astounding cures, by means of the new therapy. To put these reports to the test, to sift out fact from fiction, it was decided to complete the armamentarium of the hospital by the installation of an *x*-ray apparatus. So great has been the progress in radiotherapy within the last few years that in the treatment of skin-diseases, as in other branches of medicine, the experimental stage has given place to firmly-fixed methods of treatment. Not only has the technique been placed on a firmer basis, but, of equal importance, the cutaneous affections actually suitable for radiotherapy, have finally been collated and separted from the host of other diseases to which the human skin is liable.

At the Skin and Cancer Hospital one has ample opportunity to observe a multitude of skin-diseases, many of which are undoubtedly benefited, and most readily healed by means of the *x*-ray. It may be well to state that those diseases which we know are amenable to the medicinal and mechanical methods of treatment have been, with few exceptions, excluded from the hospital's *x*-ray clinics. Such lesions, for example, as acne, psoriasis, seborrhoic dermatitis—cases which, when properly treated, should yield to the physician's efforts—are not included in the list of dermatoses appropriate for radiotherapy. Needless to say, therefore, that a patient with such a lesion as an epithelioma of the cheek or of the forehead which can be readily and thoroughly removed in a short space of time by the surgeon is treated in the surgical, not in the *x*-ray department, of the hospital.

It is not my purpose to submit any data concerning the cases in question, nor to discuss the technique of *x*-ray exposures in diseases of the skin. Successful results can certainly not be obtained by men who have had no special training in dermatology; a certain amount of clinical experience in the handling of various forms of skin-diseases, whereby one is enabled to compare the various methods of treatment, and to draw conclusions therefrom, is essential in every radiotherapeutist. Caution, it must be said, should be the watchword of all physicians who make use of the ray. Unless a certain amount of care is exercised in the application of each exposure, and unless the effect of each séance is carefully noted, very unpleasant and obstinate burns are apt to follow the administration of this powerful remedy.

Among the most rebellious affections with which the physician has to deal, two vegetable-parasitic diseases, *ringworm* and *favus,* rank prominently as examples wherein the employment of the *x*-ray has shown brilliant results. It matters not whether the cure of these diseases is brought about through the direct destruction of the fungus, or whether the depilation following a variable number of exposures is the dominant factor; the fact remains that in cases of *favus* of the scalp, which have been unsuccessfully treated for a period extending over five years; and in cases of *tinea tonsurans* which have shown but slight, if any improvement after two years of faithful treatment, the effects of *x*-ray exposures administered during periods ranging from five to fifteen weeks have always been decidedly satisfactory. A case is pronounced "cured" when, after repeated microscopical examinations, no trace of the fungus can be discovered. This applies with equal force to disease on other portions of the hairy skin—*tinea barbæ, tinea cruris.* Many are the cases of "barber's itch" which have resisted the most painstaking treatment by lotions, pastes, and salves, clearing up in a remarkable manner after a dozen exposures to the *x*-ray.

All cases of ringworm and favus treated within the hospital are brought to the dispensary at least once a month, when a microscopical search for spores is made should any suspicious spots present themselves in areas previously diseased. Of the cases of favus and ringworm of the scalp which have been discharged as cured not one showed recurrences after a lapse of one to six months; of the cases of *tinea barbæ,* all of which are treated in the out-patient department, about one-third showed recurrences, usually of trifling extent, after a period of three to six weeks following the last exposure. This may be due to the fact that the amount of care bestowed out-patient adults cannot equal that given to the indoor cases.

Closely allied, in its clinical behavior, to *tinea barbæ,* is the so-called non-parasitic sycosis, more properly called *sycosis staphylogenes.* Many of these cases of sycosis, and of simple folliculitis of the bearded region, can be cured by comparatively few

exposure to the *x*-ray. In this class of cases it is not at all necessary to prolong the treatment up to the point of depilation, as cases frequently get well before the hair begins to fall out, and even before the slightest erythema presents itself.

In this connection, it may be worth mentioning the cases of "ingrowing hairs" frequently observed on the neck of young men who use the razor. In this condition, it seems that the obliquity of the hair follicle causes the hair to curl in on itself, setting up an inflammation, followed by a postulation in each affected follicle. If one loop of such a hair is caught with the point of a needle and drawn out it will often bring forth a spiral of hair, between one and two inches in length, more or less covered with a film of pus. Nothing in the line of local treatment can approach the *x*-ray in the cure of this anomaly of hair-growth.

In *hypertrichosis,* *x*-ray treatment has not given as good results as might be expected. Although persistent and repeated exposures will ultimately cause a permanent alopecia in the affected area, it has been found that the defluvium occurring after a series of exposures is only transient, and that, as the hair grows again, it is necessary to reexpose the patient to a number of courses before the desired result is arrived at. This procedure carries with it the risk of setting up an inflammation of the skin, ranging from a slight erythema to an intense dermatitis, and even in cases in which no unpleasant inflammatory reaction occurs, the oft-repeated exposures frequently cause the skin to assume a peculiar dry, glazed and atrophic appearance, giving the patient more discomfort and less peace of mind than the condition for which she sought relief.

Lupus vulgaris fortunately is a comparatively infrequent disease in this country, and the number of patients, most of them foreign-born, applying for treatment at this hospital, is insignificant when compared to the cases seen at the British and Continental hospitals.

Patients appear at the clinic presenting comparatively recent and superficial lesions, and involving an area ranging in extent from the size of a pea to that of a silver dollar; it seems irrational to consign such cases to the tedious and time-consuming *x*-ray exposures; it is preferable to excise or curette the lesion in one sitting, should the patient consent to the procedure, and in selected cases, to follow this up with a short course of *x*-radiation. Here, as in other diseases, the administration of internal remedies, directed against the invasion and multiplication of the tubercle bacillus, should never be neglected.

Again, there are patients, usually adults, with large, infiltrated, partially cicatrized and ulcerated areas of the disease upon the face and neck, sometimes also upon the limbs and trunk, many of whom have been previously treated by the numerous methods which have from time to time been advocated for the eradication of this disfiguring malady; these various topical methods are all more or less painful, and the cosmetic effect in the majority of cases, is anything but satisfactory. It is especially in these old and inveterate cases of the disease, in which radiotherapy, all things considered, is probably the most satisfactory method of treatment at our disposal. Here, also, it is frequently advisable to employ supplemental operative measures, such as boring, scraping, and cauterizing, in conjunction with energetic raying, so as to eradicate the disease as rapidly as possible. In children, where most of the operative measures are frequently impossible, and in patients in whom the avoidance of causing pain is a desideratum, the *x*-ray offers us the treatment of choice. Besides having the advantage of being painless, the result of treatment is a smooth, white, pliable scar, causing less disfigurement than any of the operative methods in vogue at the present time.

Although the actinic rays are considered to be superior, in some respects, to the *x*-rays in the treatment of lupus, the expense connected with the installation and maintenance of a Finsen apparatus and the infrequency of lupus vulgaris in the United States prevent this mode of treatment from being employed as commonly in America as it is in European cities. In some cases, the ultra-violet hand-lamp is used to advantage, but on the whole the *x*-ray has been found to have a wider range of usefulness, especially in cases which cannot be conveniently dehematized before the application of the ultra-violet ray. For example, in cases of lupus of the face, where the septum of the nose is involved, and in lupus of the ear, where the dehematization by means of pressure is impracticable on account of the uneven surface of the helix of the ear, *x*-radiation is undoubtedly the best remedy at our command.

Although radiotherapy undoubtedly exerts a beneficial effect upon *erythematous lupus,* the results obtained in the treatment of this disease by means of the *x*-ray are in no way comparable to those attained in lupus vulgaris. The "*x*-ray list" at this hospital, does not include lupus erythematosus, as it is believed that more satisfactory results are obtained by the employment of local operative and medicinal measures, combined with the various constitutional remedies appropriate to each patient. In a few instances, the ultra-violet iron-electrode hand-lamp has proved to be serviceable, but cured cases have not been recorded following the use of this instrument. Within recent years excellent results have been reported in erythematous lupus treated by means of high-frequency currents.

In several cases of *tuberculosis verrucosa cutis,* where operative measures were refused by the patients, the *x*-ray was applied with promising results in all, and with an apparent cure in one case. It is, however, preferable to treat these lesions on surgical principles, and, if deemed advisable, to ray the diseased area after it has been removed as thoroughly as possible by operative procedures.

In the treatment of *keloid,* *x*-radiation gives better results than any agent employed heretofore. For the small lesions frequently seen upon the chest and arms, the *x*-ray seems to be a specific. Energetic and persistent raying of these tumors will, in time, cause a complete disappearance of the growth, leaving a smooth white scar in the site of the keloid. It it sometimes necessary to push the exposures up to the point of ulceration; when the ulcer heals, and the scab drops off, a large portion of the tumor will be found to have disappeared. In the large keloids of the face, neck, and chest, the *x*-ray causes a decided softening and diminution in the size of the tumor-masses; where pain exists, *x*-radiation frequently alleviates this symptom. In the extensive, diffuse keloidal conditions following burns, the results have been unsuccessful.

The *x*-ray has shown good results in *keratosis palmaris et plantaris.* Several cases here were treated with strong salicylic acid plasters applied to the palm and sole of one side, while the *x*-ray was applied to the palm and sole of the other side. Comparing the two methods, radiotherapy showed much better results; the treatment causes no inconvenience, the effect is more lasting, and the necessity of having the hands covered with plasters and bandages is eliminated.

There are cases of chronic, indurated *eczema* affecting a part or the whole of the skin, and accompanied by severe itching which are very rebellious to

the common methods of treatment; such cases of inveterate eczema, as well as cases of *pityriasis rubra*, and the hypertrophic form of *lichen planus*, react very favorably to *x*-radiation: the pruritus disappears, the skin is softened, the induration and infiltration is lessened, the joints become limber and the general health of the patient improves markedly.

It should always be borne in mind, however, that in order to achieve the best results the proper internal and external adjuvant treatment should be carried out in all cases, and not to depend too much upon the *x*-ray. It cannot be too strongly emphasized that many of the rebellious diseases with which the dermatologist has to contend are due chiefly to errors of metabolism—that is, they are constitutional diseases with cutaneous manifestations; how obviously inconsistent it would be, therefore, to attempt the cure of a skin-disease due to systemic derangement by means of radiotherapy alone.

Since the advent of radiotherapy, the gloomy prognosis of *mycosis fungoides* has been materially altered. Although it is one of the rarest of cutaneous affections, recent literature abounds with a suspiciously large number of reported "cures" of this fatal malady. That the *x*-ray exerts a decidedly beneficial influence upon the disease there is no doubt. The hospital has had under *x*-ray treatment four cases of *mycosis fungoides;* two of these have died of nephritis and exhaustion: the other two are still under treatment, and apparently are progressing favorably. These patients showed marked subjective and objective improvement as soon as the exposures were commenced: the pruritus was relieved, tumors flattened and disappeared, ulcers healed up, weeping and indurated eczematous patches gave place to apparently sound skin, and the general health of the patients improved progressively. Despite these promising results, however, recurrences appeared in three of the four cases within a month after the cessation of the treatment. Evidently the full value of radiotherapy in *mycosis fungoides* can not be properly judged from the small number of cases treated here up to the present time.

Epithelioma of the skin has the distinction of receiving more attention in connection with radiotherapy than probably any other cutaneous lesion. Whether this distinction is really justified is a question which has brought out considerable differences of opinion among physicians who have had experience in this line of work.

A certain percentage of cases seems to derive no benefit whatever from *x*-radiation, while not a few actually become more extensive and intractable after a number of exposures have been administered; but the great majority of cutaneous epitheliomata will show most marked improvement, frequently amounting to a complete cure, after having been submitted to a variable number of exposures. In epithelioma, as in many other cutaneous lesions, it is the recent, superficial, non-extensive growth which will yield most favorably to the influence of the *x*-ray; many cases will clear up completely within a comparatively short space of time, with a cosmetic result leaving nothing to be desired; in these, the lesion is replaced by a smooth scar, usually of lighter color than the surrounding skin; in other cases, the scar is traversed by numerous telangiectases; or again, appearing so much like the normal skin that the site of the lesion can scarcely be distinguished.

The patients with malignant lesions of the skin come under two classes: those who refuse operative treatment, and those in whom surgical treatment is out of the question, on account of the extent or inaccessibility of the disease; in both these classes of patients, radiotherapy is undoubtedly the ideal mode of treatment, frequently showing surprisingly good results. Recurrences, however, either within the scar, or at its periphery, are of frequent occurrence; these recurrences will disappear upon a repetition of the exposures, but whether they will or will not return is a question which cannot, at the present time, be satisfactorily answered. It is not good policy to consign all epitheliomata to the *x*-ray, regardless of extent, location, and duration; it is the rule, at this hospital, to transfer to the surgical division all cases which appear suitable for a radical excision; after the surgeon has removed as much of the diseased area as is possible, recourse may be had to the *x*-ray, to destroy outlying cells and thus to prevent a possible recurrence in or about the scar.

In *rodent ulcer*, a disease which frequently resists all other forms of treatment, radiotherapy has shown very promising results; these cases, however, are far more intractable than simple epitheliomata, and, notwithstanding the fact that the discharge, the odor, and the pain may disappear after a comparatively small number of exposures, recurrences in or near the scar are very frequent and should be persistently reexposed.

A case of *psorospermosis follicularis* (Darier's disease) was given *x*-ray treatment, after other methods of treatment proved futile; the patient, whose feet were diseased to such an extent that walking caused much suffering, was enabled to perform her household duties without discomfort, after having received about thirty exposures.

A case of *idiopathic multiple hemorrhagic sarcoma* is now under treatment at the hospital. After only six exposures, of ten minutes' duration, to each extremity, the edema has lessened, infiltrated patches have softened, and bluish-red and violaceous patches of skin are beginning to turn pale and to take on a normal appearance. No internal treatment is being administered.

The conclusions to be drawn from the observation of the patients in the *x*-ray department of this hospital are as follows:

(1) The *x*-ray will cure ringworm and favus of the hairy skin more rapidly and reliably than any other method of treatment; the advantages of the method are, that it is painless, harmless when properly used, and thorough, and that it cuts down the expense incurred by the city in the treatment and care of these patients to a very considerable extent.

(2) Hypertrichosis should be treated with electrolysis, not with the *x*-ray.

(3) The *x*-ray gives very satisfactory results in the various forms of cutaneous tuberculosis; in keloid, in keratoses, in infiltrated patches of chronic eczema, *lichen planus, pityriasis rubra;* in the tubercles, ulcers, and tumor-masses of *mycosis fungoides*, psorospermosis and sarcoma.

(4) *x*-radiation relieves pruritus, burning, tingling, and pain; it decreases the discharge and foul odors of various dermatoses, often causing them to disappear completely.

(5) In selected cases, radiotherapy is the ideal agent in the treatment of epithelioma and rodent ulcer.

Hygiene of Spanish Churches.—The Alcalde of Madrid, who, at least in sanitary matters, is decidedly progressive, has issued an order for the disinfection of churches. This order, which is based on a report from the director of the municipal laboratory, prescribes that all the churches of the Spanish capital are to be swept out daily with sawdust moistened with a solution of copper sulphate. All the fittings and furniture of the churches—chairs, benches, confessional, holy water fonts, etc.—are to be disinfected every day.—*British Medical Journal.*

EARACHE.

By ALBERT BARDES, M.D.,

ATTENDING SURGEON AT THE NEW AMSTERDAM EYE AND EAR HOSPITAL.

NEW YORK.

The recent observation of a number of fatal cases of acute otitis media, that at first were treated in a haphazard manner by the family physician, has led me to sound a note of warning in regard to earache, that this painful symptom may receive the full attention that its seriousness deserves. No pain is capable of producing greater suffering than a severe earache, even child-bearing is less painful, and no disease is more dangerous than that of which earache is the principal symptom.

Earache is regarded far too lightly by many physicians, and in many of the neglected cases, either the termination is fatal or the hearing becomes impaired, or a chronic running ear is developed. It is wrong to regard an earache simply as a painful symptom that usually passes off as soon as the drumhead bursts. Rightly considered, it is the sign of a dangerous infection that may impair and even destroy the sense of hearing, and may even cost the very life of the sufferer.

Even to this day, most mothers look upon an earache in a child as being one of the troubles that any child may get, like measles, scarlet fever, or chickenpox, and nothing is done to relieve the trouble save to drop some laudanum or warm sweet oil into the ear. Fortunately, a child does not suffer long, for the thin drum-head soon yields to the pressure of the inflammatory exudate and the fluid escapes from the ear. Not infrequently earache in an infant is not recognized as such. The suffering is usually ascribed to the teeth, and the error is not discovered until the ear begins to discharge.

In most instances the let-alone policy of treating infantile ear troubles is attended by no bad results, but in certain cases, through lack of attention, the condition becomes serious and speedy intervention is demanded to save the hearing and perhaps the life of the patient. In former years many mothers were told that their child would outgrow an ear trouble, and they were advised to let nature take its course. That such advice is harmful, and even dangerous, is apparent to every one who treats the ear.

When we stop to think that in civilized life one person in every three has some defect in hearing, and that most of these defects date from infancy, we begin to understand the importance of treating the ears of children at the outset of the trouble. The entire surface of the middle ear, if spread out, would not be larger than a silver quarter; enclosing a space the size of a dried pea, yet this small cavity is the most useful, and at the same time the most vulnerable one of its size in the entire body, because of its close proximity to the brain and to the internal ear.

For the production of an earache two things are essential: an inflamed middle ear and an exudate that presses upon the drumhead. Normally, the middle ear is an aseptic space and its mucous lining exerts a protective influence and guards against infection. As soon, however, as there is a breach in its surface it ceases to protect; on the contrary, it favors the development of pathogenic organisms. In almost every instance the middle ear becomes diseased through the passage of infectious matter from the nose, at a time when the condition in the middle ear is abnormal.

Pathogenic germs are constant inhabitants of the nose and nasopharynx, even in health, and it requires no stretch of imagination to assume that through an expiratory blast, such as coughing, or blowing the nose, they can be forced through the inflamed eustachian tube and thus enter the ear. When sterile water is forced into the healthy middle ear by means of a eustachian catheter, no symptoms are produced other than those of a mechanical obstruction—deafness and a feeling of fullness in the ear, which gradually pass away when the fluid is drained off by the eustachian tube. Even fluid that contains infectious material fails to produce disease so long as the mucous membrane is intact. When, however, the vitality of the middle ear has been weakened by disease, the introduction of any fluid into the middle ear, even sterile water, seldom fails to set up a pathological condition.

Acute middle ear trouble usually occurs in the course of an acute infectious disease, such as scarlet fever, measles, pneumonia or grip. Scarlet fever and measles are accountable for most ear trouble in children, while grip is the prevailing cause among adults. The pernicious nasal douche and sea bathing also claim a certain number of victims, through the suction of water into the nose and into the tubes.

In scarlet fever one child out of every three develops otitis, and of half this number the affection is bilateral. When we consider that 20 per cent. of acquired deafness is due to scarlet fever and that most running ears can be traced to it, the importance of prompt measures in dealing with an otitis from this cause becomes apparent.

It was not until the severe epidemic of influenza in 1890 that our attention was called to the frequency with which otitis occurs in grip, and ever since that time the grip ear has been a common observation in the changeable weather of the spring and fall months. The otitis of influenza must be carefully watched, since the mastoid is implicated oftener than in the otitis following other diseases.

When, in the course of a febrile disease, an otitis arises, it usually begins towards the decline of the fever, when the vessels become relaxed and the mucous membrane pours out an inflammatory exudate. This occurs in the second week of influenza and measles and the third week of scarlet fever, the time when the physical condition is poor and the vitality of the ear enfeebled.

During an attack of any acute fever, involving the upper air tract, the cavities of the ear, in common with those of the nose and throat, become congested, and when the hyperemia resolves, an exudate is thrown out by the relaxed mucous membrane. Under ordinary circumstances the secretion from the middle ear is drained off by the eustachian tube and passes to the nose. When, however, this tube is inflamed and obstructed, the exudate cannot escape and soon fills the middle ear and mastoid cells. As the fluid accumulates, the pressure in the middle ear increases, and finally the drumhead bursts. In most instances the escape of the fluid marks the cessation of the pain and other inflammatory symptoms. Left to itself, the drum-head usually ruptures within twenty-four hours in children and between the third and fifth day in adults. In certain cases, however, the drumhead is firm and does not yield to the pressure of the exudate. When this occurs the fluid usually becomes infected by pyogenic organisms, and the infection may invade the mastoid cells and may even attack the lateral sinus. In very young children an infected exudate in the middle ear is particularly dangerous, because of the ease with which it destroys the thin shell of bone that separates the middle ear from the brain.

In children the mastoid process contains but one large cell, the antrum, and when it becomes diseased the pus frequently penetrates its bony cortex

and produces the well-known periosteal abscess, so common in children, and for the relief of which Wilde's incision was devised. It is a mistake to wait for a mastoid abscess to become mature, in the hope that it will evacuate itself, for frequently, even in children, the inner wall of the mastoid process becomes eroded, instead of the outer, and the pus enters the brain cavity, after which there is no certainty of a successful issue from operative procedure.

Sometimes mastoiditis occurs in spite of every precaution and an early and free incision into the drumhead. This is when the middle ear has been shut off from the mastoid cells by inflammatory adhesions so that the pus from the cells cannot escape into the middle ear. Such a condition is present when there is a bulging of Shrapnell's membrane and a sinking of the posterior superior canal wall. At times the bulging of Shrapnell's membrane is so pronounced that it hangs down like a polyp. In this class of cases, mastoid and even cranial involvement may occur in spite of precautionary measures.

The severity of most attacks of acute otitis depends largely upon the physical condition of the sufferer and the virulence of the infection. At one time it was thought that the most constant factor in fatal cases of otitis was the streptococcus, but further research has shown that no particular microbe is accountable for all severe infections. In those cases of otitis in which the exudate does not become infected, the drumhead may remain intact and the exudate escape by way of the tubes. Ankylosis of the ossicles from fibrous adhesions is sometimes observed in these cases when the exudate passes off.

Recurring attacks of otitis are usually observed in individuals who suffer from a disorder in the nose or throat. In children adenoids and tonsils are responsible for most recurring earaches. In adults the trouble lies in the turbinates or in the septum. Such persons readily take cold, and, with each cold, deafness and earache are experienced. These are the cases in which the underlying nasal disorder must first be cured before we can hope to benefit the otitis.

An acute attack of middle-ear disease usually begins with fever, not always. The ear throbs and feels full; and soon a sharp pain is felt, which is worse at night and when lying down. Dizziness, nausea, and annoying noises are also complained of. The ear is tender to the touch, and every movement of the head intensifies the pain. The canal of the ear is swollen and the hearing is poor. These symptoms continue to increase until the fluid escapes, then they quickly subside, providing the drainage is good. In young children the symptoms of an acute otitis may be obscure and misleading. It begins with a high fever, 103° or 104°, and perhaps with convulsions. The child is fretful, refuses to nurse or to lie upon the diseased ear, and puts its hand to the ear and rubs it. When the ear is accidentally touched, it utters a sharp scream, like a child suffering from meningitis.

The only satisfactory way to find out the true condition of the middle ear, especially in children, is by means of the ear speculum. All other methods are incomplete and misleading. In an acute otitis media, the drumhead, instead of being pearl-gray in color, is inflamed, and bulges at some point, usually at the posterior inferior quadrant. The landmarks on the drumhead are usually obliterated, excepting the short process of the malleus. Occasionally a whitish deposit of cast-off epithelium on the drumhead hides the inflamed surface, and when the deposit is removed with cotton, the true condition is revealed.

By placing a diagnostic tube into one's own ear and gently inflating the diseased ear of the patient, bubbles of air can be heard forcing their way through the fluid in the middle ear. A tuning fork placed upon the mastoid process of the diseased ear can be heard by the patient better than when placed over the mastoid process of the sound ear,—due to the better sound-conducting properties of the fluid medium.

As soon as a person complains of a severe earache we must bear in mind that we have to deal with a septic process, which is apt to assume dangerous proportions if allowed to go unchecked. The sufferer should be kept quiet, put to bed and placed upon a fluid diet, and in other ways treated as we would treat a patient with a high fever. The bowels are to be kept open, and a single dose of morphine given to insure rest and comfort. Dry heat or else an ice-bag can be applied to the ear. The former is the more acceptable to most patients. Every three hours the ear should be gently irrigated with a hot solution of bichloride 1 to 5,000, after which a few drops of a 12 per cent. solution of carboglycerin can be instilled. The pernicious practice of putting an onion, an oil, or a tincture into the external meatus should be discouraged, since it is not only useless, but harmful and uncleanly as well.

Under no consideration should a person be allowed to suffer longer than twenty-four hours. If the pain continues, and the drumhead is inflamed and distended, palliative measures are worse than useless, and any attempt to abort the inflammation by means other than surgical is dangerous, and valuable time is lost in so doing. A bulging drumhead should be treated in the same way as a septic formation in any other place. It should be freely incised, rather than simply punctured or allowed to break. This procedure not only gives prompt relief, but also prevents dangerous complications in most instances, and facilitates the reparative process. No operation in surgery is attended by greater relief and benefit than that which evacuates a distended middle ear, when properly done.

By administering a hypodermic injection of morphia or by giving a whiff of chloroform or nitrous oxide, the drumhead can be freely incised with little or no pain. The utmost care and cleanliness should be exercised in doing so, lest a mild infection be converted into a more serious one from without.

During the progress of a middle-ear trouble we must be on guard for symptoms of mastoid involvement. This is shown by a sagging of the posterior superior canal wall and tenderness over the mastoid process. The sagging of the canal wall is due to the detachment of the periosteum, and occurs only when pus has invaded the mastoid cells.

Clinical and Etiological Notes on Paratyphoid Infections.—Sacquépée and Chevrel present the following conclusions: The most frequent cause of paratyphoid infections is the ingestion of contaminated drinking water. Various instances demonstrate this fact—the epidemics at Tours and at Fontevrault. It has sometimes been suspected that the infection could be traced to meat. Paratyphoid fever occurs most often during the estivo-autumnal season; it is generally more severe in the autumn. The time of inoculation varies from about five to fifteen days. There are two ordinary clinical types: one is severe and simulates enteric fever. Some of the most marked clinical symptoms of this type are sudden onset, hypertrophy of the liver, and constipation; the other, a mild form, is characterized by febrile gastric disorders. The diagnosis can be made absolutely only by means of laboratory investigations.—*Gazette des Hopitaux Civils et Militaires.*

MEDICAL RECORD.

New York, January 20, 1906.

TISSUE SELECTION.

THE selective quality of the tissues is a subject which affords a most interesting and helpful study in the application of remedial agents for disease. Fränkel, in his highly interesting work, Arzneimittel-Synthese, declares that it is not alone a question of closely allied chemical relations, but ofttimes one of physiological conditions. Chloroform, for instance, tends to accumulate in the red blood corpuscles, this being due to the facility with which chloroform mixes with lecithin. Myelin or the medullary sheath of the nerve behaves in the same manner in the presence of fatty substances. The hydrocarbons, ether, and sulfon-combinations probably act in the same manner. Acids, bases, alcohols, and phenols may readily form chemical combinations with different protoplasmic groups. Fuchsin may be extracted from the kidney by alcohol. Certain tissues appropriate poisons from the blood, just as wood fiber will abstract coloring matter, such as picric acid, form a solution, however weak the solution. One theory in explanation of this fact is that the coloring matter in the fiber is not in a solid state but still in solution. Different fibers and different tissues take different colors, exerting a selective action upon the staining solution in which they are immersed. In the cells of various organs are different chemical groups, while individual substances have different capacities for selection according as they are alkaline, neutral, or acid media. These individual substances are not taken up by the protoplasms of the cells but by the intermediate substances. Substances with tertiary nitrogen which possess little or no poisonous action, may be transformed in the tissues into powerfully poisonous substances by reduction, while the same poison will most rapidly destroy that form of protoplasm which develops the greatest functional activity. The spinal cord possesses a marked selective force for strychnine. If we knew the cause of this selective force in the tissue, or were able to recognize the chemical groups in the nerve elements of the cord which arrest and retain the strychnine, as it passes through the blood vessels of the cord; if we could recognize the groups in the strychnine which are retained by the cells of the cord, we would be able to construct through synthesis substances which would only adhere (be anchored) to the cord, where they would be subject to reactions and thus produce active groups at will.

We know that definite groups of atoms in definite positions either act of themselves or produce their activity by being incorporated into other groups. Definite groupings of atoms incorporated in physiologically active substances may arrest that action entirely, weaken it, or give it other properties. The same substance may have both physiological and pathological properties. Alkaloids produce their effects in small doses. That they, however, possess selective affinity for certain tissues we know; they are rapidly excreted to a large extent, but a certain portion is retained and rendered ineffective by the liver, while traces are recognizable in many other tissues. Thus is proven the statement that the portion which produces the action is an extremely small fraction of the dose. This hypothesis would prove that the missing fraction of the alkaloid undergoes a transformation which would account for the action of the drug and a relationship between constitution and action as well as one between action and chemical transformation.

Certain drugs offer more or less resistance; when this resistance is present the drug is said to be to a greater or less degree inert. This resistance of specific drugs which act upon individual tissues appears to furnish the basis through which the selective properties of tissues are made possible; for if a drug react with all characters of protoplasm, specific results will be found impossible, the very degree of resistance of the tissues making it possible for small doses of certain substances to exert a specific action upon particular tissues, while others are not affected. Emil Fischer declares that a definite configuration is necessary for a sugar molecule in order to influence the action of particular kinds of yeast, and that the fermenting portion of the yeast molecule is related to the fermented sugar molecule as is a key to the lock. We can apply this simile to other substances which have a selective action and are decomposed by exerting it, all other tissues being unaffected.

For the production of action the concurrence of several factors is requisite, and an effective substance without customary action can be made to have such an action. It is necessary for its end-group to come in contact with organs or tissues to determine this action. The end-group which seems to anchor the substance, may or may not exert some action. The basic substance may be only a vehicle for the active atoms, which may occupy such a stereochemic position as will enable them to unite chemically with some definite group of atoms in the tissues.

This theory may be shown in that the physiological action is produced as a rule by the main portion of the molecule, by some lateral chain in the same, or by the anchoring atoms. We must therefore distinguish between two groups in every active substance. The lateral chain or residue, which unites chemically with groups of atoms in the tissues, thereby anchoring the molecule, represents one group; the other consists of those atoms which produce the physiological action. Both the anchoring and active groups may have the same grouping of atoms. If the anchoring group is closed or altered, another than the original physiological action may be exhibited, provided another anchoring group is present. This group may have relations with some other organ or tissue and be able to determine a physiological action of another character; or the entire molecule may be so modified by the change as to influence a different action. This will occur when there are several points of anchorage in a given

molecule, with several groups having a different action. The anchoring group having chemical reactivity controls the situation, or it may happen that anchorage is determined by oxidative alteration of the chemical substances.

PROPRIETARY REMEDIES.

At a meeting of one of the sections of the American Medical Association in Portland, last July, Dr. Frank Billings of Chicago presented a communication, entitled, "The Secret Nostrum Evil," recently published in a number of the State journals, in which he warns against the "menace to the welfare of the people and to the best interests of scientific medicine" contained in the flood of patent medicines and proprietary remedies now offered to the profession. He distinguishes between the patented remedies and those protected by a copyright or trademark. Concerning the former he says: "These preparations are ethical, in that they are not secret, for any one for a small fee may obtain from the patent office of the government a copy of the description of the process of manufacture and the actual chemical composition of any such patented drug or remedy." Of the copyright proprietary remedies he says: "Medicines so prepared that the busy physican could easily dispense them found a certain class of doctors eager to use them. The indications for use appeared on the label or in the accompanying literature. Tonics, blood and tissue builders, emenagogues (*sic*), pain relievers, febrifuges, laxatives, calculi dissolvers, soporifics, bile promoters, heart tonics, cures for Bright's disease, etc., have appeared in countless number, and some remedies offered are confidently presented as cures for not one but half a dozen diseases or symptoms complex."

There is an ethical distinction here without a difference. If the physician is chemist enough to understand the significance of the chemical symbols and the extremely technical details of manufacture of the patented drugs he surely is competent to analyze any of the secret proprietary mixtures and so to determine for himself their composition. To the physician who is not a chemist one class of remedies is as secret as the other. The "literature" of the manufacturers of one kind is just as extravagant in its claims as—and no more so than—that of the other, and the condemnation of one class applies with equal force to the other. The indications for use appear in the "literature" of the patented drug as they do in that of the proprietary remedy. For example, the difference in the matter of "ethics" between a well-advertised intestinal antiseptic and a certain popular proprietary tonic is as that 'twixt tweedledum and tweedledee. In each case the proof of the pudding is in the eating, and the average physician has no more definite guarantee of the therapeutic value of the one than he has of that of the other; in each case he has to rely upon the "literature" and his own experience. If he follows Dr. Billings' advice to adhere to the pharmacopeial preparation he will discard both, though the tonic, if the manufacturer had the wisdom to publish its formula, would probably be found to be compounded of pharmacopeial drugs, while the other is not yet of the *élite*.

Of the objections to some of these remedies Dr. Billings says little that is new and much that is true, but the force of his argument is weakened by a lack of judicial calm. He condemns absolutely all mixtures of any sort, of known or unknown composition, and urges their rejection by the physician and the substitution for them of extemporaneous prescriptions. The grounds upon which this rejection of ready compounded mixtures is based are that their composition is unknown, or if the ingredients are published their proportions are kept secret, or if the ingredients and quantities are published there is no guarantee that the manufacturer is telling the truth, and finally that no ready-made mixture is suitable for every case of any disease. Regarding most of these objections there can be but one opinion. The physician wishes to know what drugs he prescribes and the proportions of each in the given dose of the mixture, and he should use his own judgment concerning the indications in each case, for it is a trite saying that the patient should be treated, not the disease.

The objection, which Billings makes by indirection, that the physician cannot rely upon the statements of the manufacturer regarding the composition of his remedies is one of too general application to be tenable, and applies with at least equal force to the use of extemporaneous formulas. The physician must trust somebody, for he cannot gather his own simples and stew them into nauseous draughts. If he cannot rely upon the word of the reputable manufacturing chemist regarding the composition of his product, no more can he put confidence in the integrity of the individual pharmacist. The sin of substitution is one of which much has been said, and that it exists there can be no doubt; but the culprit is as often the retail druggist as the wholesale manufacturer. In prescribing many drugs, such as the alkaloids, the physician—we venture to say even the writer of the article from which we have quoted—often calls for tablets rather than extemporaneous solutions, and not infrequently purchases them in quantity in the original package of the manufacturer. He trusts this manufacturer to prepare him a tablet containing a definite quantity of morphine and atropine, yet he is asked not to accept the word of the same manufacturer in the case of some other mixture purporting to contain certain less powerful drugs. This is an inconsistency that renders the argument ridiculous.

That what Dr. Billings tautologically calls "the secret nostrum evil" exists we would not deny, but the remedy is simple and does not call for philippics or hysterical condemnation of every non-pharmacopeial preparation. Physicians are not children, who must be watched by a careful nurse lest they burn their fingers with matches or get sick from licking the paint off their dolly's face. They know, or should know, what to prescribe for their patients, and those among them who are so lazy or so ignorant as to prescribe according to the directions contained in the "literature" put forth by the manufacturers of patent medicines and proprietary remedies will never be deterred from such a reprehensible practice by aspersions upon the integrity of all manufacturing chemists. Nor will the compounders of secret preparations be induced to publish their formulas by indiscriminate and intemperate condemnation of all proprietary remedies, secret or open. If they are assured that there is nothing to be gained by divulging their secret they are not likely to divulge

it. But we are convinced that Dr. Billings does not voice the general sentiment of the profession on this question. If the manufacturers were to publish their formulas—not only the ingredients but the exact proportions of each—their preparations would undoubtedly find a wider acceptance by scientific physicians. Many of these now refuse to use secret remedies, but they would prefer the more elegant preparations of the pharmaceutical chemists (were the ingredients known) to extemporaneous mixtures, whenever in their judgment they met the indications in the individual case.

Skoda's Centenary.

On December 11 a memorial meeting in honor of the centennial of Joseph Skoda's birth was held in Vienna, and on the same day a monument bearing his statue was unveiled in Pilsen, his birthplace. The son of an obscure locksmith, the child who in future years was almost to revolutionize the art of medical diagnosis was already, in his tenth year, contributing to his own support by acting as teacher to his less advanced schoolfellows, and his subsequent advance along the paths of education was attended by the greatest hardship. Those to whom his name recalls only its association with the peculiar tympany heard over lung compressed by fluid, as in some cases of pneumonia, do not realize to how great an extent the diagnostic methods of to-day depend on the illuminating investigations of Skoda, which promptly gave to Vienna a preeminent position in medical instruction. Although Hippocrates had indicated the use of the sense of hearing in diagnosis by describing the method of eliciting succussion in hydropneumothorax, auscultation remained an unexploited aid until Laennec was led to experiment in this direction, and finally to invent the stethoscope, by seeing children at play amuse themselves by applying one end of a stick to the ear while a comrade scratched the other end with a pin. Even after the stethoscope had come into use and Auenbrugger had developed the art of percussion, diagnosis by these aids was not advanced greatly beyond the confines of empiricism because these clinicians sought to connect each phenomenon elicited with a special disease, thus speedily creating a complexity of terminology and observation which was urgently in need of classification. Skoda, the first clinician to court instead of shunning the supreme test of the diagnosticians' acumen by the uncompromising revelations of the deadhouse, introduced the autopsy as a routine finale to fatal cases, and taking the post-mortem knife from the usually prejudiced medical attendant who had rarely been accustomed to wield it, secured impartial verdicts by placing it in the hands of a newly created officer, the prosector or pathologist. He then instituted his comparisons of the physical signs during life with the findings after death, and, discarding the restricted views of his predecessors, sought the explanation of the various auscultatory phenomena in the broad laws of physics that govern the same manifestations outside of the human body, and rendered possible the objectivity that is so highly desirable in diagnosis. Skoda, though Hungarian by birth, was the first German clinician to throw aside the convention of ages and deliver his lectures in German instead of in Latin. Many reports of his wonderful skill have been handed down; for example, his sense of touch is said to have been so highly trained that he constantly amazed his classes by diagnosticating complicated heart lesions by palpation alone. His activities were by no means limited to the field of thoracic disease, and he was one of the first to support Semmelweiss in that ill-starred observer's attempts to place the doctrine of puerperal infection in its proper light. Prof. v. Schrötter in his address delivered before the memorial meeting of the Viennese Medical Society warmly defended Skoda's memory against the allegation that he was a therapeutic nihilist, and stated that many improvements in treatment, such as the popularization of hypodermic medication and the abolition of the almost universal practice of venesection that then prevailed, were due to his genius. Skoda died in 1881, but in 1870, when he resigned his professorial chair, he said to v. Schrötter as if in review of his life work, "now it is the turn of the microscope and of chemistry," a prediction that certainly has been fulfilled.

The Control of River Noises.

A partial victory has been gained by Mrs. Isaac L. Rice in her determined fight for nocturnal quiet, in so far as the National Board of Steam Navigation has passed a resolution to restrict the blowing of whistles by river craft to the limits of actual necessity. This does not mean, however, that the cause has been won and that there is no further need for agitation. The tugboat captains are sturdy sinners and a simple admonition from the owners to keep quiet will not effect much in the way of a lasting reform unless it is backed up by the strong arm of the law. These little boats have enormous whistles, out of all proportion to their size, and when these are blown with a steam pressure of 150 to 200 pounds, the noise emitted is terrific and can often be heard across the entire island from one river to the other. As a well-known master of one of the Albany boats writes, from 80 to 90 per cent. of this whistling is nothing less than rowdyism, and so far from being necessary is actually dangerous, causing confusion of the lawful signals. So far as this noise disturbs the rest of the people of the city and prejudices the chances of recovery of the sick, its abatement is, or should be, legitimately within the province of the Board of Health, and if Commissioner Darlington has not the authority to deal with a nuisance of this nature, it should be given to him. Unless these disturbers of the peace are restrained by the officers of the law, there is little hope of relief for the sick in the municipal institutions or for other sufferers who live along the river front. The arrest and punishment of a few of the tugboat masters who are wont to call their crews from the saloons by soul-racking shrieks of their sirens, would soon convince them and their fellows that the sending of a messenger to bring back the deckhands is an equally effectual measure and one conducive to their own comfort as well as to that of the peaceful citizens of the town.

The Cartwright Lectures.

The three Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons of New York will be given this year on January 25 and 29 and February 2, by Baron K. Takaki, ex-Surgeon-General of the Imperial Japanese Navy. The subject of the lectures will be: "Military and Naval Sanitation: Experiences Drawn from the late Japan-Russia War." This will be the first complete and authoritative account of the Japanese Naval and Military Medical Organization given in this country, and, coming from the man who was chiefly instrumental in the establishment of that incomparable service, it promises to be of unusual interest. Dr. Takaki studied medicine at St. Thomas' Hospital, London, where he was graduated with high honors, passing also the examinations of the Royal Colleges

of Physicians and of Surgeons. While in England he made a very careful study of the medical department of the British Navy, and on his return to his native country devoted all his energies to the organization of the medical and sanitary system of the new Japanese Navy. He rose rapidly to the rank of Surgeon-General and continued in active duty until the close of the Japan-China war, when he was created a baron by the Emperor in recognition of his services, especially in freeing the navy from the scourge of beriberi. Dr. Takaki has also taken an active part in the reorganization of hospital methods in Japan, and has always been a strong supporter of the Red Cross, the great strength of the society in that country being largely the result of his encouragement and support.

News of the Week.

First Aid in Time of War.—President Roosevelt has appointed a board composed of medical officers of the army and navy to consider improvements in the matter of first-aid dressings and the advisability of the adoption of a uniform equipment in the medical departments of the army and the navy. The members of this board from the army are Col. Valery Havard, assistant surgeon-general, Capt. Charles Lynch, assistant surgeon and a member of the General Staff, and Capt. Carl R. Darnall, assistant surgeon, who is in charge of the field medical supply department in Washington. Those from the navy are Medical Director John C. Wise, commanding the Naval Medical School in Washington, Surgeon Charles F. Stokes, on duty at the Naval Museum of Hygiene and Medical School in Washington, and Surgeon William C. Braisted, on duty in the Bureau of Medicine and Surgery in Washington.

The Centennial Banquet of the State Society.—The banquet to be held during the Centennial meeting of the Medical Society of the State of New York, on Wednesday evening, January 31, will be a notable occasion. Among the guests who have signified their intention of being present are: Governor Higgins, Hon. Grover Cleveland, and Drs. William Osler, W. W. Keen, L. S. McMurtry, J. H. Musser, C. A. L. Reed, and Howard Kelly. The tickets, including wine, will cost $5, and, as the number is strictly limited to five hundred, applications should be made as early as possible to Dr. William J. Nellis, 210 State street, Albany, N. Y.

Bellevue Training School for Nurses.—The commencement exercises of the Bellevue Training School for Nurses were held January 9, when twenty-eight young women received their diplomas. It was announced that the sum of $50,000, which was raised by the board of managers after considerable effort for the purpose of building a new nurses' home, can now be devoted to the running expenses of the home, inasmuch as the Board of Estimate on December 27 decided that the new home should be built by the city.

For a Children's Bureau.—A bill has been presented to the Senate and referred to the Committee on Education and Labor, having for its object the establishment of a bureau to investigate and report upon all matters pertaining to the welfare of children and child life, and especially to investigate the questions of infant mortality, the birth rate, physical degeneracy, orphanage, juvenile delinquency and juvenile courts, desertion and illegitimacy, dangerous occupations, accidents, and diseases of children of the working classes. The bill provides for the establishment of the children's bureau, to be under the direction of the Secretary of the Interior, with a chief, at $5,000 salary, an assistant chief at $2,500, and a full complement of clerks.

Dental Examination of School Children.—An interesting report has been received from Joseph J. Brittain, United States Consul at Strassburg, Germany, in which he describes the success attending the establishment in that city of a dental clinic for school children. In 1902 the city opened this clinic for the care and treatment of the teeth of the children in the public schools, and to make such care and treatment compulsory. The children are treated free of cost and are given instruction in the care of the teeth and keeping them clean. Since the establishing of the Strassburg clinic similar ones have been opened in Darmstadt, Mulhausen, and other cities in Germany, and much interest is being aroused. At the Strassburg clinic 5,343 children were examined the first year and 2,666 received treatment. The third annual report, just published, states there were 12,691 visits to the clinic in 1904 and 6,282 children were treated, for whom 7,065 teeth were filled and 7,985 were extracted, and 4,382 other children had their teeth examined. The children are taught to clean their teeth three times daily, and especially before retiring. The dentist also instructs the children in the use of the toothbrush, each child receiving a brush for home use. Since the introduction of the treatment there has been a marked improvement in the general health of the public school children.

Columbus Academy of Medicine.—At the annual meeting of the Columbus Academy of Medicine the following officers were elected: *President,* Dr. James U. Barnhill; *Vice-President,* Dr. S. J. Goodman; *Secretary,* Dr. Chas. J. Shepard (reelected); *Treasurer,* Dr. William C. Davis (reelected); *Censor,* Dr. J. A. Frame, and *Delegate to the House of Delegates of the State Association,* Dr. J. H. J. Upham. The Executive Committee in its annual report urged the establishment of a permanent home for the Academy, including a reading-room and library, in which its members might enjoy the privacy and conveniences demanded by the character of their work, and by which it would more fittingly uphold the importance and dignity of the medical profession in the community. Dr. F. F. Lawrence, the retiring President, in appropriate remarks presented Dr. D. N. Kinsman, the first President of the Academy, with a beautiful gold-headed cane, the gift of his professional friends.

Tuberculous Cattle Killed.—On January 13 thirty-one high-grade Jersey cows were killed at a fertilizer factory in Rome, N. Y., on account of tuberculous infection. The animals, which had been owned by two dairymen, were condemned by Dr. William K. Kelly, chief veterinary of the State Agricultural Department. A few months ago forty-nine Jersey cattle were killed at Rome for the same reason. When the disease is found to be only local the owner receives from the State 60 per cent. of the value, and 40 per cent. when the disease is found to be general. Where no trace of the disease is found, a premium value is paid. The milk from one of the diseased herds was being sold in New York City at a high price.

University Students in Germany.—Recent figures seem to show a considerable increase in the number of students attending the twenty-one universities of Germany. The total number of matriculated students is now 42,390, as compared with 29,117 ten years ago. The University of Berlin has the largest total, the number of matriculated students being 8,081. Bonn has 2,908 and Heidelberg 1,443. The

faculty of law was the best attended, having 12,139 students, as compared with 4,975 a decade ago. A remarkable fact is the rapid, continuous decrease in the students of Protestant theology. Within the last decade these have decreased from 4,437 to 2,186, while the students in Catholic theology have increased from 1,079 to 1,680.

Longevity.—A colored woman alleged to be one hundred and thirty-five years of age died at the Home for Aged and Infirm Negroes in Philadelphia January 6. According to the statements of her relatives, she was born on November 14, 1770, in a settlement known as Frogtown, near Valley Forge, Penn. She often told of scenes in and about the camp of Washington's soldiers at Valley Forge in the Winter of 1777-8. As is usual in reported cases of extreme old age, she is said to have used tobacco all her life. From England comes the story that Henry Johnson of Grantham, the oldest acrobat in the United Kingdom, has just entered in his hundredth year, and is still lithe and active. He has lived during the reigns of five British sovereigns.

Hospital Saturday and Sunday Association.—At the annual meeting of this association, held on January 9, at the United Charities Building, all the old officers were reelected and Isaac Guggenheim was added to the Board of Trustees. It was announced that this year's collection promised to be the largest in the history of the association, and would probably exceed $100,000. Last year it was $92,000. One prominent Fifth Avenue church alone contributed over $8,000.

Beth Israel Hospital Association.—At the annual meeting of the Board of Directors, held on January 11, the President's report showed that in 1905 the hospital received $84,133.31 and spent $84,375.85, the deficit being made up from a balance in 1904 of $2,000. Since October 1 1905, the hospital has received in subscriptions $20,000. In 1905 the hospital treated in all 45,573 persons. Eight hundred more were turned away for lack of accommodations.

Newburgh Almshouse.—So many complaints have been received in regard to the manner in which the Newburgh almshouse has been run that the State Board of Charities has appointed a committee to investigate the matter. It is alleged that the mismanagement has been largely due to political conditions.

Vital Statistics of Philadelphia.—The death-rate in Philadelphia was lower for the year 1905 than in any year since the compilation of the vital statistics of the city was begun in 1860. The mortality for the year was 17.25 in every 1,000 of population, as against 18.44 in 1904. The number of deaths from all causes was 24,807, as against 25,971 in 1904. The principal causes of death for the two years were as follows: Pneumonia, 3,361 (1904), 2,591 (1905); tuberculosis of the lungs, 3,107 (1904), 2,829 (1905); tuberculosis of other viscera, 393 (1904), 432 (1905); typhoid fever, 744 (1904), 689 (1905); diphtheria, 542 (1904), 361 (1905); scarlet fever, 201 (1904), 60 (1905).

Notification of Infectious Diseases.—Commissioner of Health Charles J. Whalen of Chicago has sent notice to the physicians in that city, directing their attention to the new law which provides that every physician who attends any person having a contagious or epidemic disease, such as cholera, yellow fever, scarlet fever, diphtheria, typhoid fever, smallpox, varioloid, puerperal fever, membranous croup, measles, or whooping-cough, shall report the case within twenty-four hours, giving the name of the patient and a description of the disease. A fee of ten cents is allowed for every report, and a penalty of from $10.00 to $200.00 may be imposed for failure to obey this law.

Mosquitos in New Jersey.—The State Entomologist of New Jersey has published the results of an extensive investigation into the mosquito problem, based on actual surveys of the great mosquito breeding grounds in the salt marshes, which fringe the State from upper Newark Bay, down along the Atlantic coast and up the Delaware Bay. It is estimated that nine-tenths of all the mosquitos in the State come from the salt marshes and that to exterminate the pests it is necessary to abolish the marshes. It is thought that the expenditure of $315,550 will be sufficient to accomplish this, the estimate being based on what has already been done in New York and New Jersey.

Health Boards in Ohio.—The recent action of numerous cities of the State of Ohio in abolishing their health boards, an action rendered possible by recent changes in legislation, has led to a concerted movement among the medical men of the State, intended to establish local sanitary supervision on a more permanent footing. A circular letter has been sent to the representatives requesting them to institute such reforms as shall place the organization of the health boards on the merit system, and render it completely independent of politics.

Tuberculosis Sanatorium for Kentuckians.—Under the auspices of the Kentucky Club of Denver, Colo., a tuberculosis sanatorium is to be founded near Denver, for the reception of tuberculous natives of Kentucky, who will receive treatment at low cost. The estimated cost of the building and grounds is placed at between $100,000 and $150,000. Of this amount the Denver Kentucky Club will contribute probably $5,000. The balance of the money, it is hoped, will be raised in Kentucky.

Tuberculosis Exhibition for Tenement Dwellers.—On January 16 a tuberculosis exhibition will be opened in the Warren Goddard Settlement House, Second avenue and Thirty-Fourth street. Much of the material used at the recent exhibition in the Museum of Natural History will be on view, and it is expected that the task of the workers among the poor in that section will be much aided by the graphic demonstrations concerning the nature of the disease and the means that must be taken to avoid and to cure it. The exhibition will continue until January 27.

The Boston Tuberculosis Exhibition.—The attendance during the Boston tuberculosis exhibition, which ended January 7, was 24,560. This is a larger number by 6,960 than attended the New York exhibition held a few weeks previously. This is an excellent showing, and no doubt demonstrates the value of wide publicity in a matter of this sort. —*Boston Medical and Surgical Journal.*

The Case of Dr. Bowditch.—A large number of prominent physicians of Boston and other places in Massachusetts have sent to the Governor a protest against the summary dismissal of Dr. V. Y. Bowditch by the trustees of the State Sanatorium at Rutland, after he had served the institution efficiently as visiting physician for seven years. The document came before Ex-Governor Douglas too late for him to take action, but he transmitted it to his successor, Governor Curtis Guild, with the indorsement that the matter required careful investigation.

Health Conditions in New York State.—According to the Bulletin of the New York State Board of

Health for November, the death rates per 1,000 of some of the large places in the State are as follows: New York City has a rate of 16.2, as compared with 14.7 for Elmira, 15 for Yonkers, 18.5 for Mount Vernon, 18.5 for Albany, 21 for Troy, 21.5 for Cohoes, 19.2 for Kingston, 20 for Newburg, 16 for Gloversville, 22 for Utica, 17.4 for Rome, 14.8 for Binghamton, 15.5 for Syracuse, 15 for Auburn, 18.3 for Ithaca, 20 for Lockport. Cobleskill has the best showing, with a rate of 11 deaths per 1,000 population, and Oswego makes the poorest showing, with the high figure of 23.5. The average for the entire State is 15.6.

Nostrum Concern in Trouble.—The so-called Medical Director and Assistant Medical Director of a quack medical concern were arrested in this city on January 12, by the Federal authorities, on a charge of conspiracy to obtain money under false pretenses by using the United States mails. The concern is one of the many that by spurious advertising induce credulous people to correspond with them, and then foist on them nostrums at exorbitant rate under conditions leading the victim to believe his case has been given individual attention. The investigation leading to the arrest had covered a period of almost a year, and has been managed jointly by the Post office authorities, Assistant United States District Attorney Clarence S. Houghton, Champe S. Andrews, and John S. Cooper, the two latter as counsel for the Medical Society of the County of New York.

Appointments at Johns Hopkins.—The trustees of Johns Hopkins Hospital have appointed Dr. Rufus I. Cole associate in medicine, Dr. Josiah M. Slemons associate in obstetrics, Dr. C. P. Emerson resident physician, and Dr. Roger Morris assistant resident physician.

Appointments at St. Luke's Hospital.—The trustees have appointed as assistant visiting physicians at St. Luke's Hospital, in this city, Drs. Walter A. Bastedo, Everett W. Gould, and Karl M. Vogel.

Obituary Notes.—Dr. Emmet Cooper Dent, Superintendent of the Manhattan State Hospital for the Insane on Ward's Island, died suddenly of heart disease on January 12. He was born in Macon, Miss., in 1857, and was graduated from the Bellevue Hospital Medical College in 1879. He was immediately appointed to the staff of the City Insane Asylum on Blackwell's Island, and in 1886 he became superintendent. In February, 1896, when the New York City Asylums were reorganized and placed under State care, he, with his hospital, was transferred to Ward's Island, continuing there as superintendent of the female department of the Manhattan State Hospital. On June 1, 1905, the two departments were consolidated by act of Legislature, and he was made superintendent and treasurer of the entire hospital as it now exists, it being the largest and most modern of its kind in existence. To Dr. Dent is due the credit of many advances and ideas in the care and treatment of the insane. He was noted at home and abroad as being the first to introduce and develop hydrotherapy as a means of treatment, almost to the entire exclusion of medicines; he also introduced camp life for the acute insane; the use of music, and of special diversions and amusements; advanced surgical care and treatment, and operative procedures, especially on the female insane. He was the author of numerous articles on the above subjects. His hospital was the first to accept the more modern views in psychiatry, and has made further advance in this feature in the way of systematic investigation in detail, and in the clinical study. Dr. Dent personally gave clinical lectures on the various types and manifestations of insanity, and he also organized his staff of thirty physicians into a society for the advanced study of psychiatry.

Dr. Carl Bendeke of Minneapolis, Minn., died on January 5 after an operation for an affection of the kidneys. Dr. Bendeke was born in Christiana, Nowray, in 1841. He came to this country in 1868 and went at once to Chicago, where he began the practice of medicine. In 1876 he went to Minnesota, removing to Minneapolis in 1877, where he had remained ever since.

Dr. S. T. Yancy of Fortville, Ind., died on January 3, at the age of seventy-two years. He was a well-known physician and conspicuous in medical circles in his early days. He served as State Oil Inspector in 1884, and represented Hancock County in the State Senate in 1881.

Dr. Lehman H. Dunning of Indianapolis, Ind., died of angina pectoris on January 4. Dr. Dunning was born at Edwardsburg, Mich., in 1850. He was graduated from Rush Medical College, Chicago, in 1872, and began the practice of medicine at Troy, Mich. In 1878 he removed to South Bend, where he remained until going to Indianapolis in 1890, when he succeeded Dr. T. B. Harvey as lecturer on gynecology at the Indiana Medical College. He had for some years been regarded as one of the most prominent gynecologists of the State.

Dr. Thomas W. Simmons of Hagerstown, Maryland, died on December 30, at the age of sixty-nine years after an operation for intestinal obstruction. He was graduated from the Jefferson Medical College in 1861, and since 1864 had been practising in Hagerstown. He had held numerous positions in local medical affairs.

Dr. George W. Doane of Hyannis, Mass., died on January 4, at the age of eighty years. He was a lineal descendant of Deacon John Doane who settled in Eastham in 1644. He was graduated from the Harvard Medical School in 1844, and at once began practice in Hyannis, which he never left. Of late years he had given up practice and spent his time in travel.

Dr. Harrison Hathaway of Toledo, Ohio, was instantly killed by a railroad train on January 4, at the age of sixty-four years. Dr. Hathaway was a native of Seneca County but had practised in Toledo for over thirty years.

Dr. Orlando S. Strange, the oldest physician in Kingston, Ont., died on January 2 after a long illness, at the age of eighty years. He had practised in Kingston for over half a century, and was mayor of the city in 1859.

Dr. W. R. Blue of Louisville, Ky., died on January at Rome, Ga., where he had been for some weeks on account of ill health. Dr. Blue was born forty years ago in Gallatin, Tenn., and had practised in Louisville for the last fifteen years.

Dr. Calvin Snook of Fairfield, Ia., died on January 4, after a short illness. He was graduated from the College of Physicians and Surgeons, Keokuk, Ia., in 1869. He was active in municipal affairs and at the time of his death was a member of the City Council. He was also a member of the Board of Health for a number of years.

Dr. David R. Davis died at Lansford, Pa., on January 5. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1893.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL FUNDS—SUPPOSED EFFECT OF AN INTERNAL SECRETION OF THE MAMMÆ ON THE FETUS—PYOSALPINX WITH CALCULUS IN THE APPENDIX—STANDARDIZATION OF DRUGS—ANALYSIS OF VIOLET LEAVES—LEICESTER'S SHORT WATER SUPPLY—ROYAL INSTITUTE OF PUBLIC HEALTH—INSANITY IN IRELAND.

LONDON, December 29, 1905.

A QUARTERLY report of the Hospital Saturday Fund circulated yesterday shows that up to December 9 the receipts showed an increase of more than £1,000 above the amount of last year. The report states that the three hospital funds (the King's, the Sunday, and the Saturday) are drawing closer together and working on similar lines as far as the three constitutions permit. The committee thinks that hospital abuse is not so extensive as has been stated, and hopes the restrictions imposed on out-patients will not hinder the most suitable cases obtaining relief. The proposed amalgamation of small special hospitals is referred to, and the steps taken as to the orthopedic institutions approved. Negotiations are now going on as to the five institutions doing work for throat and ear cases. It has often been suggested that a central hospital board should be established. As to that, the report before me says the duties of such a board are admirably performed by the King's Fund, with the cooperation and assistance of the other two hospital funds, and good will result from this to both the hospitals and the public. It looks as if the three funds might as well amalgamate, a suggestion I have often made. It might prove easier to accomplish this than to amalgamate a number of small special hospitals.

At the Pathological Society, on the 19th inst., Mr. S. G. Shattock communicated the results of some experiments made five years ago to decide whether the breasts during pregnancy furnish an internal secretion which is necessary for the growth of the fetus. The mammary glands were removed from guinea pigs, the ducts being cut across close to the nipple. The operation was easy; in some cases necrosis followed the extensive raising of the skin, although the wounds were carefully sutured and closed with gauze and collodion. In three animals the wound completely healed and a male was put to each. One became pregnant and brought forth three young, two of full size. One of these was fed artificially and lived for six days, from which Mr. Shattock concluded that the mammary glands do not furnish an internal secretion necessary for the growth of the fetus during the pregnancy.

Dr. T. G. Brodie could hardly accept this conclusion, and thought it probable that the ovary was concerned with the activity of the breast, though the question is still unsettled.

Both Mr. Shattock and Dr. Brodie referred to the work of Dr. Starling, who you will remember injected regularly extracts of fetal rabbit tissues for considerable periods into virgin rabbits. Enlargements of the mammary glands followed, comparable to that seen in pregnant rabbits, but not invariably. In fact, a number of his cases furnished only negative results, though, of course, positive results in some cases are not without significance.

At the Gynecological Society, on the 14th inst., Dr. Richard Smith showed a specimen consisting of a pyosalpinx, perforated appendix, and a small stone, which had escaped during operation. The patient five years ago had an attack of appendicitis during a pregnancy, and had suffered from dysmenorrhea since. Another attack occurring, a hard tender mass was found in the right iliac region, but there were no rigors nor pyrexia. There was intense pain on movement. Inflamed appendix adherent to the tube and ovary was diagnosed. On opening the abdomen, the omentum was found adherent. On separating it, a dense mass of tissue appeared, from which a swollen tube was released without rupturing it, but between it and the appendix was a small abscess cavity containing a couple of drams of pus. On dissecting away the appendix, the small calculus escaped through a perforation. The pus was removed with gauze. No flushing; no drainage. Recovery was quite regular, the wound healed on the tenth day.

Mr. C. Ryall said in his experience adhesions to the female pelvic organs were rather common and would be more often noted if they were looked for at every laparotomy. Dr. C. H. F. Routh had once found a large piece of cecum, apparently including the appendix, in a large abscess he had opened.

Mr. B. Jessett had seen many cases of adhesions to various viscera. He approved swabbing rather than flushing.

Dr. R. Smith in his reply said the entire Fallopian tube was included in the tumor. He thought the most interesting point was that pyrexia was never once observed throughout.

The biochemical standardization of drugs has been discussed recently at the Therapeutical Society and a resolution adopted to the effect that it is "most desirable that those who are responsible for the British Pharmacopeia should take steps to insure the physiological standardization of drugs, particularly of digitalis, squills, strophanthus, ergot, and cannabis indica." It was argued at the same meeting that chemists should prepare and standardize their tinctures instead of procuring them from wholesale houses. Dr. Dixon, who put forward this opinion, had found great differences in specimens obtained from different sources. Some preparations were quite inert, while others differed so much in strength as to render their use dangerous. The modern tendency has placed so much in the hands of the wholesale manufacturers that the retail chemists are giving away that branch of knowledge which is their chief claim on the public. They cry out that doctors might hand over their dispensing to them, and they are themselves handing over their scientific work to others. It is comparatively a small number of pharmacists who really continue to do this important part of their work.

At a subsequent meeting of this society, on the 19th inst., Mr. H. W. Gadd reported the result of a research he had made on the chemistry of violet leaves. A glucoside had previously been found by Mandelin, who named it "viola quercitrin, which can be split up into quercetrin and glucose. Mr. Gadd found the glucoside. He did not find and volatile constituent, or salicylic acid, or any alkaloid. The glucoside amounted to about 5 per cent. of the fresh leaves. Nine-tenths of this could be extracted from the leaves by infusion. Although salicylic acid could not be detected, there were indications of a phenol. The varieties of the cultivated violets vary somewhat in the amount of glucoside.

The people of Leicester are in a very unpleasant predicament and the health authorities at their wits' end. The insufficient rainfall has entailed a shortage of water supply which becomes more threatening every day. The supply has been obliged to be curtailed for some time and is now cut off for 10 hours in the 24. Of three reservoirs, one is down to the dregs and the other two have only one-fourth of their normal amount. About 300,000 gallons are obtained from a colliery shaft, but that is not nearly enough. Another well has been sunk from which 200,000 gallons per day is being pumped, but unhappily the site of this is near a cemetery and the public are naturally apprehensive. The water has been analyzed and pronounced good, but the danger is obvious, for it is stated that bodies have been buried this week within a stone's throw of the well. The population is 267,000, so that contamination would mean a sad disaster. Another supply, it is hoped, will be obtained within two months. Leicester is engaged in carrying out a great scheme for supplying its needs from the Derwent Valley, but it will be six years before that will be completed. The deficient rainfall this year seems, therefore, the more distressing.

The Royal Institute of Public Health has now arranged for examinations and reports of chemical, microscopical, and bacteriological specimens to be supplied to practitioners at moderate charges. The investigations will be undertaken in the new laboratories, and no doubt will be appreciated by busy men.

The Blue-Book, relating to lunacy in Ireland, shows a continued increase. This has been going on for a whole generation. A special inquiry has lately been conducted into the facts and a report will no doubt shortly be made. The present Blue-Book gives many statistics, from which it may be deduced that the number of insane under care increased from 250 per 100,000 of the population in 1880 to 522 in 1904. If to these be added the number of lunatics and idiots at large, the figures would be 610 per 100,000. Various neuroses are becoming more common in Ireland, particularly general paralysis of the insane, mainly a disease of town life.

An Appendix to Sartor Resartus.—A writer has contributed to *St. George's Hospital Gazette* a prospectus of a proposed work on the pathology and treatment of diseases and accidents of the toilet. The prospectus is fortified by alleged extracts from the forthcoming volume. Among the lesions described are "perforating ulcer of the sock," "false passages of the vest," "hairy mole of the shirt-cuff," "idiopathic atrophy of the pajamas," "sloughing of the posterior foramen of the collar-band," and "prolapsus trouseri," while a further chapter is said to be devoted to affections peculiar to evening dress, such as "Addison's disease of the shirt-front" "madura pump" and "inoperable volvulus of the necktie." With regard to perforating ulcer of the sock, "treatment by simple suture or the purse-string ligature is not to be recommended. Each perforation must be carefully grafted by an expert."

OUR PARIS LETTER.

(From Our Special Correspondent.)

OPENING OF THE CLAUDE BERNARD HOSPITAL—ANTITUBERCULOUS VACCINATION EXPERIMENTS—ELECTION OF GILBERT AND OF DOLÉRIS, AND EULOGY ON PANAS AT THE ACADEMY OF MEDICINE—THE NEW CHAIR OF CLINICAL THERAPEUTICS AT THE FACULTY OF MEDICINE—ANASTOMOSIS OF THE SMALL INTESTINE WITH THE RECTUM—A CASE OF PERSISTENT BILIARY FISTULA CURED BY THE ANASTOMOSIS OF THE DUCTUS COMMUNIS CHOLEDOCHUS WITH THE DUODENUM—DIAGNOSIS AND TREATMENT OF CALCULI OF THE TERMINAL PART OF THE DUCTUS COMMUNIS CHOLEDOCHUS—EXPERIMENTS WITH SYPHILITIC VIRUS—MEETING OF THE MEDICAL INTERNES OF THE PARIS HOSPITALS—THE REGIONAL AND COMFIRMED LOCALIZATIONS OF SYPHILIS.

PARIS, December 30, 1905.

ON November 30, 1905, the President of the Republic opened the new hospital for contagious diseases which has been built on the old site of the Hospital of the Porte d'Aubervilliers. This institution is a memorial to Claude Bernard. The length of the building is almost one kilometer. This hospital will receive patients ill with contagious diseases. Its construction and arrangement bear witness to the great progress in hospital building made by the Department of Public Charities of Paris. The building consists of a series of pavilions. The floor is entirely tiled, and sharp angles are avoided, the corners being rounded. Heating is accomplished by steam at low pressure, and electric lights are used. Perhaps the most interesting feature of the hospital is the method of disinfection of sewage. This disinfection is accomplished by apparatus which has been constructed by Bréchot. This apparatus consists of a cylinder the walls of which are made of a layer of coke forming a large filter which retains the solid matter while allowing liquid to pass through it. The liquid is carried into a cistern where it is sterilized by chemical processes and is finally poured into the sewer by a pump. The solid matters retained in this apparatus are burned with the coke, which is raised to a temperature of 1,200 degrees. This method of disinfection shows true progress.

On December 3, at Melun, under the direction of Valée, autopsies of calves which had been subjected for a year to the inoculations of Behring's vaccine were performed. These experiments, conducted in the most rigorously scientific manner, have proved that all the vaccinated animals remained for a year free from any tuberculous infection, all of them at this time having been exposed to tuberculosis, some by living with tuberculous animals, others by inoculations of virulent cultures of Koch's bacilli. Control animals placed under the same conditions all contracted tuberculosis. These experiments prove that we are now in possession of an antituberculous vaccine of indisputable value. It is to be hoped that antituberculous vaccination is a fact both scientifically and practically established.

Gilbert, professor of Therapeutics at the Faculty of Medicine of Paris, has been elected to the Academy of Medicine. The important works of this scholar on the pathology of the liver are too well known to be emphasized here. Doléris has also been nominated as a titular member of the Section of Obstetrics. During its last meetings the Academy has been specially occupied with reports concerning the prizes. On December 12, the annual public meeting took place, Léon Colin presiding. At this time the prizes were awarded. This impressive meeting was closed by an eulogy on Panas, Professor of Ophthalmology at the Faculté de Médecine of Paris. Panas had been dead three years. The eulogy was delivered by Jaccoud, Secretary of the Academy of Medicine. The Academy then elected its officers. Gautier, the well-known chemist, was elected vice-president. Duguet and Pinard were elected members of the Council.

At the Faculté de Médecine, the Committee of the University of Paris which met in extra session at the Sorbonne accepted unanimously the donation presented by le Duc de Louhet for the founding of a new chair of clinical therapeutics.

At the Surgical Society, Terrier made an important communication concerning his results in the anastomosis of the small intestine and rectum in cases of inoperable cancer of the large intestine. Terrier has statistics of eleven cases, eight of which are his own, the other three being those of his assistant Gosset. Of these eleven patients, three died. One had septic peritonitis, while the death of the other two was due to carcinomatous metastases. As to the eight patients who survived, Terrier was able in one case to remove secondarily the neoplasm which was located on the cecum. In the seven other patients, a simple lateral anastomosis was performed without exclusion, properly speaking, and which allowed a continuous passage through the two segments of the intestine above and below the tumor. Terrier concludes that in all cases of neoplasm of the large intestine, every time that there is a place under the lesion large enough to allow an ileorectal anastomosis it is a great advantage to practice this in preference to the formation of an artificial anus. Following the communication of Terrier, Piqué said that he thought that there was not a single surgeon who did not consider an artificial anus a makeshift and who did not seek a way of avoiding it. Besides all of the inconveniences of the artificial anus, it should be added that there have been cases of suicide and of mental disturbance in those with some predisposition to such tendencies, following the formation of an artificial anus.

Brin, of Angers, reported an important observation concerning a case of persistent biliary fistula which was cured by anastomosis of the ductus communis choledochus with the duodenum. He spoke of a patient, a woman, who had suffered with cholelithiasis for a number of years, and who, following two surgical interventions on the biliary passages, lost all of the bile from her liver through a persistent fistula. Brin performed an operation. He recognized that the fistula was located in the ductus communis choledochus, and he concluded that this canal was obstructed at its lower extremity. He decided to connect the duct with the intestine. Four days later the feces were colored and three weeks afterward the patient left the hospital completely cured.

After this communication, Tuffier discussed the diagnosis and the treatment of calculi of the terminal part of the ductus communis choledochus. In one case he broke up the calculus through the wall of the canal and the results of the procedure were excellent. In the other cases he made an anastomosis between this canal and the duodenum. Terrier believes that the method of the future in the surgical treatment of biliary lithiasis will be to open and explore systematically all of the biliary passages, beginning with the gall-bladder and ending with the ductus communis choledochus.

In the Annals of the Pasteur Institute, Metchnikoff and Roux, referring to their experiments on monkeys, discuss a question of considerable importance in human prophylaxis. They have demonstrated that if one hour after inoculating a monkey with syphilis, friction be made over the inoculated spot with a mercurial ointment, contamination of the animal will be avoided. Human beings who have exposed themselves to this disease, may have the advantage of rubbing on the exposed region without delay a calomel ointment. These experiments scientifically and rigorously conducted in relation to various species of monkeys have shown in a positive manner that local treatment with mercurial ointment of the parts contaminated with syphilitic virus prevents infection. As a confirmation of these interesting experiments, the control animals were inoculated with the same syphilitic virus taken from the indurated chancres of persons afflicted with syphilis. All of these control animals presented after the ordinary period of induration typical syphilitic chancres. The calomel ointment seemed to annihilate the ordinary action of the virus. On the other hand, the application of sublimate solution one hour after inoculation was shown to be without effect.

On December 18, there was a meeting for the purpose of nominating the titular internes of the hospitals of Paris. The names of six hundred candidates were enrolled. Four hundred and forty-three papers were returned. The question for discussion in anatomy was the ductus communis choledochus; in pathology, the semeiology of ascites. The importance of this meeting, which was of interest to the young medical world of Paris, was emphasized in a letter to the MEDICAL RECORD last year. At the Society of Internes of the Paris Hospitals, Dieulafoy discussed the regional localizations of syphilis, dwelling especially on the external localizations of tertiary syphilis. He showed that in a large number of cases syphilis confined itself to one region without any other manifestation. During extremely long periods syphilis remained constant to the anatomopathological type that it assumed in the beginning. Under the influence of appropriate treatment, an organ which appeared irremediably affected might regain its function. In regard to this disease one should never despair concerning the success of treatment.

RADIUM ACTIVITIES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—While not assuming to act as censor on matters pertaining to radium-therapy I cannot refrain from criticising the statement made by Dr. Myron Metzenbaum (MEDICAL RECORD, January 6, 1905), that the results from tubes of low activity and high activity are identical. This is absolutely at variance with the experience of operators having had large clinical experience with radium, and is practically controverted by the excellent report of the results obtained by Dr. Robert Abbe contained in the same number of the MEDICAL RECORD. Dr. Abbe's remarkable results are due to the exceptionally large quantity and high activity

of his radium, and I venture the statement that his tubes of 150 milligrammes, 300,000 activity, are not for sale at any price. He would never have been able to secure the brilliant results he reported and demonstrated with radium of low activity, and Dr. Metzenbaum's statement, if accepted by the profession, will be apt to bring radium-therapy into discredit, as the results looked for will not materialize. Only high activity radium in sufficient quantity or radium emanations secured by the new method of Lieber (radium coatings) have thus far been found efficient in the treatment of the diseases enumerated by Drs. Abbe and Metzenbaum, the emanations from radium of low activity having but little value in therapeutics as at present applied.

Three Cases of Perforated Gastric Ulcer; Gastroenterostomy.—These cases are reported by D. F. Jones. The first, a woman of thirty-two, died three weeks after operation A small perforation appeared, nine days after operation, an inch below the original one, in that portion of the stomach presenting in the wound. It gradually enlarged, and later a third appeared below the second. It was impossible to properly nourish the patient, and death resulted from exhaustion. The second patient was a man of forty-eight; operation; recovery. A like fortunate result occurred in the third case, a young man of twenty-five. The various features of each case are detailed in the respective clinical histories. The special reasons for the value of gastroenterostomy in perforated ulcers are thus summarized: The ulcer is in an active state and presumably will continue to be active for some time regardless of treatment. Rest in bed, resting of the stomach, and feeding by rectal enemata cannot arrest the activity of the ulcer at once, and so long as the ulcerations remain active there is danger from hemorrhage, perforation of other ulcers, and involvement of the sutures closing the ulcer causing leakage. In spite of the experimental findings of Cannon and Blake that the greater portion of food is forced through the pylorus after a gastroenterostomy, there must be some change produced by the operation which relieves the irritation of the ulcer, for it does give the greatest relief at once, and so far as we have any means of telling, the ulcer has a much better chance to heal.

Analysis of One Hundred and Twenty Cases of Malaria Occurring at Camp Gregg, Philippine Islands.—In an exhaustive report by W. P. Chamberlain, the following facts are brought to light: The great prevalence of malaria under the conditions named in the paper was due to the presence of large numbers of anopheles mosquitos. Infection from drinking water could be excluded. The jungle approached so close to the camp that it was impossible to drain off the breeding pools, the dangerous character of which was augmented by the long-continued wet season. The season from May to December was especially productive of the malady, the severity being most marked in October and November. Pernicious forms were very rare, owing to the thorough and prolonged treatment of the primary infection. The author notes that quinine sulphate in solution .5 gm. three times or even four times a week did not in all cases prevent infection or relapse. Malarial infections, both benign and malignant, existing for several days without chills or chilliness but with marked periodical febrile paroxysms, were by no means infrequent. Clinically the estivoautumnal infections could be clearly divided into remittent, quotidian intermittent, and tertian intermittent Of 62 cases 40 per cent. were tertians, 25 per cent. quotidians, and 35 per cent. remittents. In 46 per cent. of the estivoautumnal tertian intermittents a pseudocrisis and precritical rise of temperature was present in one or more paroxysms as shown by three hours chart. An almost identical pseudocrisis and precritical rise was observed in 9 per cent. of the benign tertian intermittents. No distinctive differences were observed in the parasites in the intermittent tertian and intermittent quotidian estivoautumnal infections. Nausea, vomiting, and abdominal pain at time of paroxysm were extremely common in both benign and malignant infections. In 120 cases, analyzed nausea occurred in 72 per cent., vomiting in 42 per cent., and abdominal pain in 30 per cent.

New York Medical Journal, January 13, 1906.

Friedreich's Ataxia.—Thirteen cases are reported by Wharton Sinkler, who gives a general description of the malady, and the histories of his cases. He refers to the disease as a chronic degeneration, resulting from a defective development of the spinal cord. It is distinctly a family disease, though no one exciting cause can be assigned. It usually develops about puberty. Autopsies have shown the amount of development in the various systems of fibers in the spinal cord and an inherent or congenital tendency to degeneration in the motor neurons. The cord is usually thin and small, and a thickening of the pia mater, especially about the posterior surface, is observed. Sclerotic changes exist throughout the whole length of the posterior columns and sometimes extend to the lateral columns. In some patients other tracts of the cord are affected, such as the anteromedian columns, but as a rule the tracts principally involved are the posterior and lateral columns, and in patients with advanced cases the medulla shows extension of the sclerosis, but the most characteristic change is the involvement in the cells of the hypoglossal nucleus. It has been asserted that in all patients suffering from Friedreich's ataxis there are secondary changes in the cerebellum present, but this view is not universally accepted. The symptoms and clinical course of the malady are portrayed by the author, who adds that it is an incurable affection, and that treatment is practically restricted to hygienic measures. Massage, electricity, and arsenic are all beneficial.

Reflex Neuroses with Special Reference to the Vermiform Appendix.—E. H. Grandin refers to the reflex symptoms arising from the coccyx, clitoris, uterus and appendages, kidneys, and vermiform appendix, illustrating his statements by reference to personal cases. He believes that the appendix is often responsible through a reflex or mechanical interference with the proper function of the cecum, ileum, and colon for gastrointestinal symptoms, which stomach washing fails to cure. The chain of events may be: Mechanical interference with the function of the bowel, constipation, colitis, tympanites, torpor-dyspepsia and varied neuroses. Several clinical histories are given. Often appendices, which examination shows are the seat merely of caloric inflammation, may contract adhesions to surrounding organs, and so set up the disturbances referred to.

The Pathological Physiology of Typhoid Fever.—The ideas of J. M. Barach are embraced in the following main propositions: The evidence of to-day is sufficient to establish the modern idea that typhoid fever is a disease dependent essentially upon the bacteremia. The Peyer's patches and solitary follicles are not the sources from which the typhoid bacilli are sent out into the circulation, but their marked involvement is due to their peculiar histological structure or to some physiological relation that exists between the typhoid bacilli and the lymphoid elements. Perforation with the ordinary pyogenic infection, staphylococci and streptococci, is much more dangerous than with the pathogenic infection, because to the latter there is already a partial immunity established. The diazo is a reaction to an end product, the result of rapid tissue destruction which is characteristic of all marked cases of typhoid fever, and of those other diseased conditions in which the reaction occurs.

Gonorrheal Rheumatism.—M. Ware gives a general description of this disase, calling attention to the diagnosis, saying that in every obscure joint affection we should look to the urine. This will often clear up the matter, especially with men in whom we can be more searching than in women. The author declares that in many a gonorrheal arthritis, chronic and relapsing, is designated as rheumatism or gout, when the introduction of the finger in the rectum will detect an enlarged and tender prostate followed by the escape of purulent discharge from the urethra, or a urine laden with shreds and threads which heretofore have been absent from it, and which not infrequently after this manipulation continue to make their appearance. In women, married or otherwise, we may elicit a history of scalding urination or a specimen which is cloudy. If the woman consents to examination, the presence of urethral caruncles and small petechial hemorrhages in the vaginal mucous membrane (referred to by Bumm as macula gonorrhoica) even though the discharge be slight, constitute valuable corroborative evidence as to the gonorrheal nature of the arthritis. The existence of a gonorrheal iritis may have to be taken into consideration to clinch the diagnosis of a doubtful arthropathy. Finally, the question arises, Are we justified in aspirating a joint to establish a diagnosis? Be it answered that only if the aspiration is indicated for the relief of symptoms and then it may be resorted to incidentally for the chances of other infection are too great and the possibility of obtaining a growth even on the best of media is fraught with much uncertainty in the outcome of the results.

American Medicine, January 13, 1906.

Should the Youth of This Country Be Instructed in a Knowledge of Sexual Physiology and Hygiene?—Prince

A. Morrow says the general principle is laid down that the education of the public is the most valuable of all measures for the prevention of communicable diseases. Its importance is emphasized in the case of diseases the communication of which lies entirely within the control of the individual. The object of the proposed education is to give the youth of this country a clear comprehension of certain physiological truths which have a direct bearing upon the regulation of their sexual lives and of the serious consequences in the shape of disease and death which follow a breach of hygienic laws. In other words, it is to teach them how to live according to the laws of a healthy nature. This instruction in the physiology and hygiene of the sex function should form an essential integral part of the education of youth. Dr. Morrow criticises our present educational system the policy of which is to launch the young into the world in complete ignorance of everything pertaining to the laws of life reproduction. In seeking this knowledge the youth is but obeying a law of his mental evolution. Since this knowledge cannot be had from legitimate sources—from parents and instructors—it is gained surreptitiously and usually from depraved sources, dissolute companions, or erotic or quackish literature. To be salutary as a safeguard, therefore, this hygienic education should be given in youth, for it is during this period that the foundations of what may be termed the "sexual character" are laid and habits of mind and practices are formed which, in a great measure, determine the future sexual life of the individual.

Medical Treatment of Abdominal Pain Not of Gastric Origin.—James E. Talley discusses the medical treatment in these cases. He states that nowhere else is an absolutely accurate differential diagnosis more difficult than in the upper quadrants of the abdomen. He takes up in turn the discussion of hernias, functional neuroses, intoxications, abdominal pain not due to disease below the diaphragm, hepatic conditions, renal pain (nephrolithiasis, floating kidney, intermittent hydronephrosis, pyelitis), intestinal conditions, pancreas, spleen, peritonitis, and pelvic conditions. Ectopic pregnancy must also be borne in mind as a possible cause of sudden abdominal pain.

Cerebellar Tumor.—Burton Chance reports a case in a man of twenty-six. The symptoms were those of intracranial tumor of the hind-brain, rather than of the more forward portions, and appear to be those produced by irritation rather than by the destruction of the basilar centers. Although an intense papillitis which was present, was conclusive of the presence of a tumor, the indefiniteness of the other symptoms hindered the assumption that the tumor occupied the cerebellar region. The chief focal symptoms were those of deviation of the optic axes, with disturbances of direct and binocular vision, and facial palsy; yet, after energetic treatment the paresis of the left external rectus muscle, as well as the diplopia and the facial palsy, greatly disappeared, and when the man was placed under strict hospital regimen the general symptoms all but ceased, for there were no headaches, emesis, or muscular spasms, until the last course. The gait, station, and the knee-jerks were not interfered with until very late in the progress of the malady. There was hyperexcitation of the sexual function almost until the end. The general bodily nutrition was maintained up to the last weeks of the man's life. A report of an examination of the brain made by Dr. Spiller is appended.

A Young Stage of the American Hookworm—Eight to Twelve Days After Skin Infection in Rabbits and Dogs.—Ch. Wardell Stiles and Joseph Goldberger have succeeded in infecting dogs and rabbits with the American hookworm (*Necator americanus*, Stiles) by placing the second larval stage of this worm on the skin of the back and guarding against any infection through the mouth. The young worms penetrated the skin, and eight to twelve days later they were found in the stomach and small intestine. They had undergone a third ecdysis and reached the fourth larval stage (with provisional buccal capsule). The authors state that there is at present no evidence that these hookworms would reach maturity in dogs and rabbits, hence the conclusion that dogs and rabbits play any rôle in spreading the disease to man is not justified by any facts known.

Journal of the American Medical Association, January 13, 1906.

The Pathology of the Kidney.—W. T. Councilman first notices the complex structure and circulation of the kidney, its excessive blood supply, its marked capacity for repair with slight capacity for complete regeneration of tissue, and the steady impairment of its structure with advancing age, due not only to arterial disease and wearing out, but also to the cumulative effect of slight lesions with constantly increasing inability to repair. The most easily understood kidney lesions are local ones from bacterial invasion, either by way of the blood or through the urinary tract. Chronic congestion and urinary obstruction may also cause damage through pressure and interference with the circulation. How the damage constantly accompanying diffuse arteriosclerosis is produced is not known. The changes consist in destruction and degeneration of the parenchyma and increase of interstitial tissue, the latter being now generally accepted as secondary to the former. There is no evidence of an independent increase of connective tissue in arteriosclerosis. It is probable that the condition in the kidneys is the result of many factors rather than of any one. The greatest difficulty in understanding the pathology of the kidney is found in the acute, subacute, and chronic diffuse lesions not connected with changes in the flow of blood or urine, nor with the immediate action of bacteria. Among these are noticed the acute interstitial non-suppurative nephritis due to the deposition and proliferation in the renal interstitial tissue of lymphoid cells from the bone marrow, spleen, etc., which occurs in acute infectious diseases, notably in the acute exanthemata. Why these cells accumulate in the renal veins is not known. Epithelial degeneration in varying character and degree is the most frequent condition met with in all cases of diffuse nephritis, often exquisitely focal and sometimes remarkably selective. Thus in diabetes, it only affects the cells of Henle's loops. The degeneration may range from very slight change to complete necrosis. Of the severer lesions of the kidney due to the diffuse action of soluble substances, Councilman notes one group in which glomerular lesions are most prominent. The most common cause of the glomerular affections he believes to be the acute infections. They may be acute, subacute, or chronic. The other form of chronic nephritis, chronic interstitial nephritis causing a slow destruction of all parts of the kidney, the glomeruli least and secondarily, with a marked increase of connective tissue, is usually accompanied by arteriosclerosis. It is a composite disease; not one organ, but many are affected. In this connection he gives the results of the anatomic study of the autopsies in cases of nephritis at the Boston City Hospital during the past ten years, and notices especially the marked heart enlargement in this form. The cases of amyloid infiltration are closely associated with it, but there is absence of heart hypertrophy. In the cases of chronic glomerular (parenchymatous) nephritis there also appeared to be a degree of cardiac hypertrophy, though to a less degree. The frequent association of acute glomerular nephritis with pneumococcal infection is remarked, as also that of the acute interstitial form with diphtheria. Certain conclusions are forced on one, he says, by the careful examination of the kidneys, in a large number of autopsies. One is that the kidney affection is only a part of a more general morbid condition. Kidney diseases cannot be considered as an entity; even the simplest bacterial lesions are secondary to infections elsewhere. Every acute infection probably leaves its traces in the kidney. Albumin and casts, though they mean injury to the organ, do not always indicate the severity of the condition, and too much importance may be attached to their occurrence. It is difficult to explain the association of lesions shown at autopsies, the cardiac hypertrophy and edema, and the numerous hypotheses that have been offered show our ignorance. It is not probable that anatomic studies can throw much light on the obscure problems of renal pathology. Clinical, pathological, chemical, and anatomic methods must all be used, and the hypotheses offered tested by animal experiments. Only thus, and by reducing the questions to their simplest components, can such knowledge of chronic diseases as will permit us to form acceptable hypotheses for their explanation be obtained.

The Operative Treatment of Fractures.—J. A. Kelly advocates the more general adoption of the operative treatment of fractures. Its advantages are enumerated by him as follows: 1. Relief of pain from movement of fractured ends and from tension due to extravasated blood. 2. The possibility of accurately approximating and retaining in position the fractured portions of bones. 3. Prevention of shortening and deformity. 4. The possibility of removing clots and repairing neighboring structures. 5. Excessive callus formation is prevented, and in fractures involving joints, subsequent limitation of motion and deformity is also prevented. 6. Pressure on adjoining structures is removed. 7. Associated dislocations may be properly reduced. 8. The period of disability is considerably lessened. 9. The skeletal mechanics of the patient are left as before the fracture. These advantages, he thinks, vastly outweigh the possible dangers of infection, of necrosis of the fractured ends, and of an external scar. When conservative methods fail to insure perfect approximation and retention and when the preservation of the skeletal mechanism is important, especially in laborers, there should be no hesitancy, he says, in converting a closed fracture into an open one. The technique of the operative methods is given in detail. Kelly prefers ab-

sorbable sutures for uniting the bones, and as all methods require some sort of external retentive apparatus, it would seem, he says, that the ideal form of internal fixation is by the heavy (No 4) chromicized catgut. The operative treatment of open fractures and of separated epiphyses and fractures associated with dislocations is also described as well as the after-treatment of all forms of operated fractures. Details of twenty-three cases, including open and closed fractures, ununited fractures, and post-fracture deformities are given. In conclusion, he remarks that proper selection should be made of cases for operative methods; most cases can be successfully managed by conservative treatment, and do not call for operation. The article is illustrated with many skiagraphs.

Streptococcus Infections.—G. F. Ruediger has made further studies, in addition to those previously published by him, of streptococcus infection in the human subject, with special reference to determining what factors are concerned in the destruction of the invading germs. He finds that although human serum during life is a good culture medium for streptococci, normal defibrinated blood has a slight streptococcidal power, roughly proportional to the leucocytosis. Human serum does not acquire any streptococcidal power in the course of a streptococcus infection, nor does the blister fluid from erysipelas have any such action. The destruction of the cocci in the defibrinated blood is brought about by the leucocytes, but the cocci must be acted on first by the opsonin of the serum. There is no phagocytosis, and hence no destruction of unsensitized cocci by washed leucocytes. The opsonin is increased during an attack of erysipelas. In acute nephritis it is decreased and the leucocytes are also affected, rendering them less effective in the destruction of the streptococci. This fact, Ruediger says, may help to throw light on the cause of many terminal infections.

Paroxysmal Tachycardia.—C. C. Warden reports in detail two cases of paroxysmal tachycardia, in which other previously unrecognized symptoms of exophthalmic goiter were present, and suggests that a more thorough examination of other cases will reveal similar relationships in a considerable proportion of instances. The more he sees of this symptomatic disturbance, the less inclined is he to regard it as a definite entity deserving a separate place in the category of disease. Its relation to exophthalmic goiter, he thinks, has not been sufficiently recognized in the past, and many of the cases reported in the literature as paroxysmal tachycardia would probably be better classed under the head of exophthalmic goiter.

Strychnine and Nitroglycerin in Circulatory Disorders.—O. H. Brown notices the mistake that is made sometimes in the use of these remedies in cases of circulatory disorder. He describes the mechanism of blood pressure, both in the general circulation and in the heart. Strychnine, acting on the vasomotor center, constricts the arterioles, causing a rise of blood pressure and a better coronary circulation, a better nutrition of the heart and a more efficient systole. Only exceptionally does it so stimulate the inhibitory vagus center as to produce no rise of arterial tension. Nitroglycerin, on the other hand, he states, dilates the arterioles, lowering blood pressure and aiding the heart by reducing the resistance against which it works. The two drugs are directly opposed to each other in their action on the circulation, and when one is indicated for its therapeutic effects the other is contraindicated. Strychnine is called for when there is a low blood pressure, a rapid heart and bounding and easily compressible pulse; nitroglycerin is indicated when the arterial tension is high, the heart rates low, the pulse full and tense and the wave very slight. In case of muscular degeneration of the musculature of the heart the signs might be slightly different from the above.

The Lancet, December 30, 1906.

Acute Poisoning by Oil of Eucalyptus.—Notes on two cases are given by F. L. Benham. One was that of a man of forty years, who took, by mistake, an undetermined quantity of the oil, about one dram being swallowed the rest being rejected, owing to its pungency. He quickly became unconscious, looking as if in a state of surgical anesthesia. Vomiting was absent. He was roused sufficiently to swallow an emetic, which acted promptly. In a few hours he was all right. The second case was practically a repetition of the foregoing. The author knows of no fatal cases.

Melæna Neonatorum; Recovery.—E. F. Heap reports the case of a male child, healthy in every way as far as could be noted, who about twenty hours after birth brought up considerable red blood and passed considerable from the bowel. No cause therefor could be determined. The child did not seem to suffer from the hemorrhage, was warm, and a little pale. He was ordered to be kept warm and quiet and to be given sips of plain water. Bleeding came on again in three hours, more severely than before with all the symptoms of intense anemia. Fifteen minims each of castor and olive oil were given in the hope of reducing blood pressure, and ice water was administered in constant sips. Bleeding stopped, though dark clots were passed constantly. Temperature remained at about 100° F. Next morning the ice was discontinued and the child given egg water and diluted milk. From this time the child steadily improved, though the problem of feeding was a difficult one. At the end of three weeks, while still anemic and weak, he was doing fairly well. Six weeks later he seemed to be in perfect health.

Acute Hemorrhagic Pancreatitis.—H. V. Munster gives the history of the case of a man of fifty-four years, thick set and stout. During the three years antecedent to his pancreatitis, he had had five or six attacks of severe abdominal pain, regarded as due to inflammation of the bowels. The present attack be an in the same way. He vomited some while his bowels moved after castor oil. The next morning he went into collapse, had incessant thirst, vomited black blood, and presented all the signs of an intestinal perforation. All the usual resuscitative measures were employed, including hypodermoclysis and adrenalin internally, and for a time there seemed to be some hope of pulling him through. It was thought that there had been a perforation of the posterior wall of the stomach, and that the ulcer so formed had become adherent to underlying structures. In a few days more, however, he again failed, and died on the eleventh day of his attack. Autopsy showed fatty necrosis in the peritoneum, while the pancreas was enlarged. There was much extravasation of blood around it and it was studded with hemorrhages. The omental nodules reacted for fat, under the copper acetate test. The diagnosis made was the one named in the title. The case is of interest, owing to its duration. The disease usually terminates fatally within five days. There was the typical bowel sequence of first constipation and later diarrhea with delirium at the close of the symptoms.

The Medical Treatment of Uterine Fibroids and Its Limitations.—T. Wilson discusses some of the statistics of fibroid tumors and their clinical course. The drugs most frequently used in its treatment are ergot and its various derivations. Some cases considered as fibroid tumors and as non-syphilitic, have cleared up under the iodide of potash. Bichloride of mercury has also been given. While not much can be hoped for from the direct effects of medical treatment, it is often possible to alleviate their symptoms, and in this way to postpone operation and possibly prevent it altogether. For hemorrhage, we order rest, ergot, and make applications of iodine to the endometrium. Hot douches, with some mild antiseptic added, are of service; as is also a hot bag, applied to the lower dorsal or lumbar spine. Of all drugs, ergot is incomparably the best. It must be remembered that it is not a safe drug to give to patients with weak hearts. In a small percentage of cases curetting of the endometrium is the best course to follow, or iodine may be injected. The author prefers iodine to other caustics for the application, because it is at the same time a reliable antiseptic and a good hemostatic, and also because it does not give rise to more than a thin superficial necrosis of the endometrium. The application can be repeated once a week in the intervals between the periodical losses. As to relieving pain, we must search out its cause and act accordingly. The pre-menstrual congestive pain is often relieved by the administration of salines in conjunction, if necessary, with the milder sedatives, such as the bromides; and by the use of hot foot baths, with or without the addition of mustard; an effective aperient is frequently of conspicuous service. The spasmodic menstrual pain in severe cases calls imperatively for rest and the application of heat to the lower abdomen. Antispasmodics, sedatives, and diffusible stimulants, are the classes of useful drugs. Of the diffusible stimulants gin is, of course, the most renowned and at the same time one of the most objectionable; alcohol in any form is often useful but always, if possible, to be avoided. Aromatic spirit of ammonia, spirit of ether, and spirit of chloroform are sometimes useful. Hoffman's anodyne, the compound spirit of ether, in half-drachm doses, is one of the most efficacious means of relieving the pain. As regards sedatives the milder ones should at first be tried, such as the bromides, antipyrin, phenacetin, or antifebrin; if these fail, or the case is a severe one, chloral, chlorodyne, belladonna, opium, or morphine, may be administered by suppository or enema, or finally, even by hypodermic injection.

British Medical Journal, December 30, 1905.

A Preliminary Inquiry into the Tonicity of the Muscle Fibers of the Heart.—James Mackenzie concludes that dilatation of the heart is not due to a mechanical dis-

tention of the chambers of the heart. There is little doubt when dilatation does occur that there will be found depression in the function of tonicity. The author adds that in stating that dilatation is an evidence of depression of tonicity only a part of the truth is presented, for the enlargement of the heart, which is associated with dilatation, depends upon the affection of certain portions only of the musculature of the heart. It has been shown that the heart-muscle fibers are distinct from the skeletal muscle in that according to their special duties certain parts have individual functions more developed than do other parts. Some have such functions as rhythmicity, conjunctivity, or contractility more developed, while it is fairly certain that some have the function of tonicity more developed than others have. As the integrity of the valvular apparatus depends upon the tonicity of the muscle fibers forming the auriculo ventricular rings, the cause of the functional murmurs at the mitral and tricuspid orifices may be explained as due to a depression of tonicity affecting these muscle fibers. The writer declares that the most striking instances of depression of tonicity occur with the failure of compensation which is seen in cases of valvular disease, the dilatation being the main evidence. Exhaustion of the muscle doubtless plays the principal part in such cases. One of the cases mentioned in this article is one in which there existed both a depression of tonicity and of conductivity during a profound anemic condition. Both functions were restored upon the disappearance of the anemia.

The Parathyroids in Graves's Disease.—S. G. Shattock gives a description of a specimen of exophthalmic goiter. The microscopic sections of the parathyroid showed groups of fat cells rather abundantly scattered through the proper glandular tissue. The latter was so compact as to resemble superficially, lymphatic tissue. Well-formed arterioles in conspicuous numbers ran in the primary trabeculæ of the interstitial connective tissue. The gland cells were polyhedral, the cell body of good size, and furnished with a spherical nucleus. At the borders of the intraglandular trabeculæ of connective tissue there was a certain grouping with no definite arrangement of the gland cells, brought about by the penetration of the capillaries into the mass. No trace of lumen in the cell groups was to be seen. The writer believes that the condition of the parathyroid in this case may be regarded as the regular one.

On the Pathogenic Ticks Concerned in the Distribution of Disease in Man.—R. Newstead gives the following list of ticks which are concerned in the transmission of human diseases: *Ornithodoros moubata*, *Argas persicus*, and *Dermacentor reticulatus*. The complete life-cycle, with much valuable information regarding the habits of the former, which is concerned in the transmission of spirillum fever in man has been thoroughly worked out. The writer presents in detail the differential characters of this tick. Very little is known of the Miana bug (*Argas persicus*) with regard to its injury to man. However, it is said to be a terrible scourge to travelers, both in Persia and Beluchistan. This species, or a closely related one, *A. miniatus*, is also responsible for the transmission of the spirillosis of the domestic fowl. *Dermacentor reticulatus* is the tick which was thought by Anderson to be responsible for the transmission of spotted fever or tick fever in the region of the Rocky Mountains in America. The theory of this investigator was founded on the ground that the fever was always found where there was a history of tick bites about a week before the onset of the fever. This claim has not been substantiated.

Hyperpyrexia Following Traumatism.—R. E. Humphry reports this case. The patient was a big burly man, thirty-two years old, who was struck when in a stooping posture on the nape of his neck, occiput, and upper part of the shoulders, by a sack of ashes weighing seventy-two pounds, which fell from a height of twenty-two feet. Twelve hours after the accident, breathing was labored and stertorous. Respirations were thirty-eight per minute, with tendency to Cheyne-Stokes rhythm. Both costal and diaphragmatic movements were impaired. The pulse was one hundred and fifty regular, in force and rhythm, but was becoming weaker, smaller, and ill-sustained with a slight dicrotic wave. The temperature taken in the axilla and between the thighs was 109.1° F. No twitching of the facial muscles was seen. The heart sounds were good but many adventitious sounds could be heard in both lungs. The pupils were equal, a little contracted, and looked straight forward. The abdomen was rather distended and tympanitic. A post-mortem examination could not be made. The writer surmises that the thermogenic, vagus, and phrenic nerve centers in the medulla were functionally disturbed, or otherwise influenced as a result of the concussion.

Intestinal Sand.—Percy W. G. Shelley describes this case. The patient, a woman sixty-two years old, first complained of acute intermittent pains in the stomach, and constipation. A tumor could be felt near the pyloric end of the stomach. Diagnosis of cancer of the pylorus was made. Three months later diarrhea set in and the motions consisted of fecal matter, mucus, blood, and undigested particles of food. Certain round bodies about an eighth of an inch in diameter, smooth, round, and of a dark-brown color, and extremely hard began to appear; they were regarded as intestinal sand. Death occurred soon after the appearance of the secondary growth. The writer states that possibly the sand was formed because the larger intestine in such cases has to assume abnormal functions such as that of the elimination of phosphates.

Berliner klinische Wochenschrift, December 25, 1905.

New Questions in the Epidemiology of Typhoid.—Kutscher, in discussing the epidemiology of typhoid fever, says that the more careful supervision of water supplies has been followed by an already noticeable diminution in the number of typhoid epidemics. More and more prominence in the dissemination of infection is, however, being assumed by the so-called "bacilli carriers." These are individuals who, while apparently healthy, harbor in their bodies large numbers of typhoid bacilli which they continually spread by their excretions. According to Lentz about 4 per cent. of all the cases, bacteriologically studied, were to be regarded as chronic bacilli carriers, and in many of these it was not possible to determine whether or not they had formerly gone through with a manifest typhoid infection. It appears that women oftener serve as permanent hosts to the typhoid bacillus than men. No method has yet been discovered by means of which it is possible to free the bacilli carriers from organisms. Internal medication always has only a temporary effect showing that the bacilli must be concealed in some situation inaccessible to the drugs ordinarily given by mouth. Both experiments on animals and post-mortem examinations on typhoid cadavers indicate that the gall-bladder probably affords the lurking place for the typhoid bacilli. Another element in the spread of the disease to which greater importance is being attached now than formerly is the matter of contact infection. It has often been observed that in limited outbreaks of the disease those infected have been only persons who have come into more or less intimate contact with the first patient, whereas other inhabitants of the same village who have used the same water or milk supplies have remained free from the disease. It accordingly appears that greater attention than before must be paid to the isolation of patients, and the thorough disinfection of all linen, dishes, and other articles coming in contact with the patient, as well as the excretions. The attendants of the sick person must also exercise particular caution in disinfecting their hands. The bacilli carriers present a more difficult problem to deal with, but it is evident that strenuous efforts must be made to prevent infection of others in this way. They must be enjoined to dispose of their urine and feces properly, and must also be debarred from occupations concerned in the production of food products and especially of milk.

Affections of the Pancreas in Diabetes.—Hirschfeld, in discussing this subject, says that pancreatic diabetes may be assumed when there is interference with the absorption of food, especially if impaired absorption of the albumins and fats proves a disorder of the secretions of the pancreas, and also in cases in which attacks of pancreatic disturbance are observed. In diagnosing such affections of the pancreas, attacks of pain are especially important, and these must be distinguished from gallstone colic, angina pectoris, and gastric affections. The attacks of pain are often so slight that the patients do not mention them unless questioned. An acute exacerbation of the diabetic condition which cannot be explained on other grounds is strong evidence in favor of pancreatic disease. Another important diagnostic sign is the presence of circulatory disturbances evidenced by the absence of an increased secretion of urine after large amounts of fluids have been taken. This test can be applied only after the acute manifestations have subsided; in some such cases edema of the extremities may also be observed. The pancreatic attacks usually last from one to four months, and ordinarily the prognosis is good; there is, however, a pronounced tendency to relapse, and sometimes the damage to the excretory function for carbohydrates remains permanent. The pancreatic involvement may also lead to the onset of fatal coma.

Münchener medizinische Wochenschrift, December 26, 1905.

The Hot Air Treatment of Pelvic Inflammations.—Jung reports on 120 cases of this sort treated by con-

servative means in the Gynecological Clinic at Greifswald. The apparatus employed was based on that designed by Polano for the application of Bier's principles of hot air treatment. Of the 120 cases 25 showed little or no improvement, and in 13 a subsequent operation was necessary. This was owing, however, to the social position of the patients, which rendered the shorter convalescence following radical procedures preferable to the longer period of absence from work demanded by the conservative treatment. After deducting these unsatisfactory cases the proportion of instances in which success followed the treatment is about 80 per cent. In regard to the indications for the operation the author says that pelvic exudates with inflammatory conditions about the adnexa, chronic adhesive pelvic peritonitis, chronic parametritis and post-operative exudates about pelvic stumps, are all favorable conditions. If pus is present it is advisable to perform a vaginal incision for drainage and then to use the hot air treatment after subsidence of any acute manifestations. The hot air treatment is not at all suitable for acute cases, in which it is likely to do more harm than good. It is also not to be recommended in tuberculous conditions of the pelvic organs. While the author does not wish to discredit surgical procedures or the older methods of conservative treatment, he considers that the hot air principle is one of great value and that its application should be further extended in gynecological practice.

Acetone Imbedding Methods.—Brunk speaks very highly of the value of acetone as an agent for use in the preparation of microscopic sections. It is well adapted as a substitute for the much more expensive absolute alcohol, and in some respects is superior to it. He describes the following rapid method of fixation and imbedding, which permits the preparation of very thin paraffin sections in from 40 to 80 minutes. The bits of tissue, which should be as small as possible, are placed without previous fixation directly into a closed bottle of pure acetone having at its bottom a layer of exsiccated copper sulphate covered with blotting paper. According to the size and structure of the specimens they remain in the acetone for from 20 to 50 minutes, or until on pressing them between the fingers it appears that they are uniformly hardened. They are then put into xylol for from 5 to 10 minutes, a step which slightly complicates the procedure but adds greatly to the rapidity with which the paraffin permeates the tissue. From the xylol the specimens are put into paraffin and may be blocked in from 15 to 20 minutes. Unlike alcohol, acetone does not require to be used in graded strengths in order to avoid shrinkage. Any of the ordinary methods of fixation may also be used if desired in connection with the acetone process.

Brachialgia.—Brassert calls attention to this affection which he says Oppenheim has several times described and stated to be relatively frequent. The affection is a purely psychic, unilateral, diffuse pain in the arm, which does not follow definite nerve tracts. It develops on a neuropathic basis and is usually accompanied by other nervous symptoms. It must be diagnosed from neuralgia, neuritis, spinal affections, as well as from disease of the bones, vertebræ, joints and muscles. The author describes a case of this sort which originated in a neurotic young mechanic, who presented no definite symptoms except the ostensibly severe brachial pain; this was alleged to have followed the appearance of a small reddish area on the forearm. Various forms of local and anodyne treatment were employed without the slightest effect. The diagnosis then became clear and the patient was ordered to use the arm freely, local applications were stopped and systematic treatment by hydriatic procedures, etc., directed to the general neurasthenia was substituted. Complete disappearance of the disability and pain promptly followed. The author explains the development of the symptoms in this case through the patient's concentration of mind on what probably was a furuncle, and the associated idea of attendant painfulness. As soon as the attention was diverted from the region affected recovery was rapid. It is suggested that the so-called reflex neuralgia often accompanying finger injuries may be of the same nature.

Deutsche medizinische Wochenschrift, December 28, 1905.

The Serum Treatment of Scarlatina.—Schick strongly urges a more extended application of Moser's antistreptococcic serum treatment in scarlatina. This has already been made the subject of extensive trial with satisfactory results in Russia, where epidemics of scarlatina of severe type are especially frequent. Schick reports 60 cases in which the serum was used, with a mortality of 16.6 per cent.; these were, however, the 60 severest and least hopeful cases out of 660 instances of the disease. In other words, the serum was used only in cases in which there was no hope from other methods of treatment and in which there seemed nothing to lose and everything to gain. The usual dose was that first recommended by Moser, 200. c c., though in two instances double that amount was injected. A serum reaction was noted in about three-quarters of the cases but it was nearly always slight and never interfered with convalescence

Chancre of the Eyelid.—Kowalewski, in discussing the occurrence of extragenital chancres says that primary lesions of the eyelid occupy only the sixth place in the order of frequency, following the lips, breast, interior of the mouth, finger, hand and tonsil. Of persons with syphilitic ocular affections chancre is observed only once in from 3,000 to 10,000 cases. He describes the case of a young woman who for six weeks had been treated by various physicians for an ulcerated area situated on the upper eyelid. The author's diagnosis of syphilis was soon confirmed by the appearance of a roseola and the patient's admission that she had permitted a male acquaintance to kiss her about the eyes and cheeks. Under mercurial treatment administered by hypodermic injection the rash promptly disappeared and the local lesion very soon healed completely. Microscopic preparations made from the surface and also from the deeper layers of the ulcer revealed the *Spirochæta pallida* in large numbers, as did also smears made from the abdominal and genital papules. Fluid obtained by aspiration from the enlarged cervical glands did not contain any of the organisms. At a latter examination, after three injections of bichloride of mercury had been given, no spirochetes could be found in a large number of smears made from the local lesion. The author emphasizes the value of the spirochetes as a diagnostic index in doubtful cases of this sort.

French and Italian Journals.

Some Hygienic Precautions in the Late War Between Russia and Japan.—Laval states that the vessels which were equipped with evaporators used distilled water. The other ships, such as the torpedoes, were furnished with water by two ships which were equipped with distilling apparatus which could produce about three hundred tons of water daily, and which accommodated 5,000 tons of water. With this supply the ships never lacked water. As to recreation, the men were encouraged on all possible occasions to sing military songs and to practice jiu jitsu. The only infectious diseases which made their appearance were enteric fever and dysentery. Even in times of peace typhoid fever has occurred. The average occurrence of such diseases in peace was not greatly exceeded during the war. The total number of cases were two hundred and forty-one. The men who were attacked were put on the hospital ships and their possessions were carefully disinfected. A few cases of dysentery broke out in August and September, 1904, during the siege of Port Arthur. Suzuki thought that flies were responsible for this light epidemic. These insects literally invaded the ships when they approached the Chinese junks for inspection. Strict measures were taken to destroy the flies, and meat was well baked before it was consumed. The dysentery disappeared almost immediately.—*Le Caducée*, December 2, 1905.

Apyretic Basal Pleuropulmonary Congestions as a Forerunner of Tuberculosis.—Vennat calls attention to a special form of pleuropulmonary congestion which he has observed in fifteen patients from fifteen to twenty-five years of age. The beginning of this infection is insidious. It is characterized by emaciation, asthenia, dyspnea, a dry and rare cough, and complete apyrexia. Examination reveals dullness, friction rubs, and râles. The evolution is slow and it is only when the general condition becomes improved that the pulmonary symptoms become ameliorated. Indeed it is the ordinary treatment of beginning pulmonary tuberculosis that is indicated. In a few of these cases heredity is a strong factor. On account of the slight functional symptoms which are manifested in this affection very careful auscultation should be practised on these cases.—*Le Bulletin Médical*, December 2, 1905.

Pulmonary Hypertrophy.—R. Tarantini tells us that in certain pathological conditions there is a limited hypertrophy of some of the tissues of the lung. In young individuals in whom, either by disease of the lung or pleura, the work of one lung is diminished and impeded, the other lung undergoes compensatory hypertrophy. An emphysema may follow this compensation, just as the dilated heart follows hypertrophy, and insufficiency sets in. Impeded function of one lung of a young animal causes the other to hypertrophy. There is increase of the elastic and muscular fibers, thickening of the vessel walls and increase in size of the alveolar lumen. It is not possible to state whether there is a formation of new alveoli.—*Il Policlinico*, December, 1905.

Book Reviews.

Précis de Laryngologie, Clinique et Thérapeutique, par le Dr. P. Lacroix, membre de la Société de Laryngologie et d'Otologie de Paris. Paris: F. R. de Rudeval, 1906.

This work follows familiar lines. It comprises four parts; the first is devoted to general methods of examination, diagnosis, and treatment; the second treats of the pathology of the pharynx, the third, that of the larynx, while in the fourth the author discusses the syndromes of laryngeal dyspnea, hemoptysis, throat cough, disphagia, affections of the voice and of speech. It is in a sense a clinical synthesis of the two preceding parts. Nothing essentially new as to fact is presented, but the work as a whole is a full and complete exposition of modern laryngology. For American students and practitioners, it offers no advantages over works produced in our own country, except as it may present the subject from the French point of view; and the well-rounded man does well to look at his subject from all points of view.

Chirurgie Oto-Rhino-Laryngologique, par Georges Laurens, Ancien Assistant d'Oto-rhino-laryngologie des Hôpitaux de Paris. Avec 470 figures dans le texte. Paris: G. Steinheil, 1906.

In this ponderous volume is presented a complete exposition of the modern surgery of the ear, nose, and throat. Preliminary chapters are given on the general subjects of illumination of the special fields, anesthesia, asepsis, and hemostasis. Then follow the special applications of these facts together with full descriptions of the various surgical procedures. Such publications can manifestly contain little that is essentially new, for they are built up from current literature and are designed to preserve that clinical knowledge which has proved itself to be of permanent value. Most of the illustrations, however, have been prepared expressly for this work and many of them have the charm of freshness, not being mere reproductions from older text books. We may mention as of especial value the sections on sinus disease, otocerebral complications, and laryngotracheal conditions, including bronchoscopy. The advance in the last decade in the field of surgical intervention in maladies of these regions has been very marked and the exposition of these portions of the general subject is fully up to date. Prof. Laurens' own contributions to literature have been many and valuable, and his name is sufficient guarantee of both the literary excellence and the professional value of the chapters he has here collected. Many operations which have been but briefly mentioned in the current journals are here figured and described with the utmost minuteness. Mere historical matter has been omitted. The consequence is that the work is an encyclopedia which will long remain the standard work of reference in this special field.

A Manual of Chemistry, Inorganic and Organic, Covering the Synopses of the Conjoint Board and the Society of Apothecaries. By Arthur P. Luff, M.D., B.Sc. Lond.), F.R.C.P., F.I.C, Physician to St Mary's Hospital, and Lecturer on Medical Jurisprudence in the Medical School; and Frederic James M. Page, B.Sc. (Lond.), F.I.C., Associate of the Royal School of Mines, Lecturer on Chemistry and Physics in the London Hospital Medical College, Examiner on Chemistry and Physics to the Society of Apothecaries, London, etc. Illustrated with forty-three engravings. Third edition, revised throughout. Chicago: W. T. Keener & Co., 1905.

As indicated in the title, this manual is designed for medical students who have to take the examination in Chemistry before the Conjoint Board or the Society of Apothecaries. To such, the book will be of value. Others may also find it of assistance in acquiring a sound knowledge of the fundamental principles of Chemistry. The book is well prepared, explanations of terms are clear and concise, there is an unusually large number of equations, and the book concludes with some useful tables for the analysis of a simple salt and of a substance containing two bases.

Operative Surgery, for Students and Practitioners. By John J. McGrath, M.D., Professor of Surgical Anatomy and Operative Surgery at the New York Post-Graduate Medical School, Surgeon to the Harlem, Post-Graduate and Columbus Hospitals, New York. Second Edition. Philadelphia: F. A. Davis Company, 1906.

A practical knowledge of anatomy is essential to the proper study of surgery, and in this volume the effort has been made to combine the two, excluding, however, on so doing the strictly technical aspect of the former. The second edition of Dr. McGrath's book contains much new matter relating chiefly to abdominal surgery and to recent advances in prostatic surgery. The entire domain of surgery is included in the work, with the exception of the gynecological operations. The illustrations are numerous and largely diagrammatic, but amply serve the purposes of the text. The latter is marked by conciseness and the book as a whole may be commended as a practical manual for the purpose for which it is intended.

Radiotherapy in Skin Disease. By Dr. J. Belot. With a preface by Dr. L. Brocq, Physician to the Broca Hospital, Paris. Translated by W. Deane Butcher, M.R.C.S., Surgeon to the London Skin Hospital. Only authorized translation from the second French Edition. With thirteen plates and twenty-eight illustrations. London: Rebman, Limited; New York: Rebman Company, 1905.

Since the original of this work was reviewed in these columns last year we can refer to the favorable estimate then put upon the text. As to the work of the translator, Dr. Butcher, we can say that he has done well, in a task not free from difficulties. Any work loses more or less of its personality, so to speak, in being transposed into another tongue, but here it would appear that this loss has been reduced to a minimum. The intricate descriptions of apparatus and mathematical formulas and equations have been reproduced with painstaking accuracy. The quantities of rays administered are throughout referred to in terms based upon the unit of the Holzknecht chromoradiometer. This has the advantage of enabling the author to enter into repeated long explanations and offers a scientific basis for comparisons. On the whole, the work is one of merit and practical utility.

The Prevention of Senility and a Sanitary Outlook. By Sir James Crichton-Browne, M.D., LL.D., F.R.S., Lord Chancellor's Visitor in Lunacy. London: Macmillan and Co.; New York: The Macmillan Company, 1905.

This little book contains two addresses delivered by the author to audiences drawn together by their interest in vital economy. The essay on "Senility" is the shorter, but the more interesting of the two—at least to those who have passed Osler's dead line. It contains nothing very startling nor any new rules for the preservation of youth, but it puts the old rules in a pleasant way. Dr. Osler gets a few gentle raps and Metchnikoff and his macrophages are dismissed with contumely. Sir James will have none of the sour milk diet. He commends life insurance for the "composure of mind it has secured," but he evidently did not have in mind the presidents and other officers of the New York companies in these latter days of stress and distress. In the essay on "A Sanitary Outlook," the author takes a sober but hopeful view of what sanitary science has accomplished and will accomplish for the good of dwellers in city and country. The addresses are very readable, and the author has done well to widen his audience by offering them in a form accessible to those who had not the privilege of hearing them at the time they were delivered.

Faulty Diction, or Errors in the Use of the English Language and How to Correct Them. By Thos. H. Russell, LL.B., Editor-in-Chief of Webster's Imperial Dictionary. Chicago: Geo. W. Ogilvie & Co., 1905.

This little book of "vest-pocket" size contains a great deal of very useful information regarding the correct use of the English language. Illustrating the comprehensive treatment that has been given the subject by the author, there are 1017 headings treated in the book, under some of which —"plurals" for instance— over fifty errors that are not at all unusual are to be found illustrated and corrected. A commendable feature of the book is its moderation. The author insists upon the correct use of language, but he does not demand a slavish adherence to rule to the destruction of freedom in diction: "It must ever be borne in mind," he says, "that the English language rebels against hard-and-fast rules," and for this the idiomatic writer owes him thanks. The book will be found of service to every one who respects his mother tongue and would avoid its misuse.

Nouveau Traité de Médecine et de Thérapeutique, publié en fascicules sous la direction de MM. P. Brouardel et A. Gilbert, Professeurs à la Faculté de médecine de Paris. Maladies Exotiques; par MM. Netter, Mosny, Deschamps, Thoinot, Wurtz, Vaillard, Hallopeau, Jeanselme, Guiart, Lancereaux, Richardière. Avec 28 figures intercalées dans le texte. Paris: J. B. Baillière et Fils, 1905.

The diseases discussed in this volume are: Typhus, relapsing, yellow and Malta fevers, plague, Asiatic cholera, dengue, kala azar, dysentery, tropical diarrheas, leprosy, yaws, Peruvian wart, Madura foot, filariasis, billiarzia, scurvy, beriberi, lathyrism, and a few miscellaneous and minor troubles. The more important of these conditions are very fully treated; the information is, as a rule, of the latest; the amount of space alloted to each topic is well proportioned; and in all respects the volume is one which reflects credit on the authors and editors. The work is to be completed in forty volumes, of which this is the sixth.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 26, 1905.

Dr. Floyd M. Crandall in the Chair.

The evening was devoted to papers on digestive disorders and abdominal pain from the standpoint of the surgeon (surgical conditions frequently occurring in the practice of physicians).

Ulcer and Cancer of the Stomach.—Dr. Charles N. Dowd read this paper. (See page 91.)

The Gall-Bladder, Pancreas and Gastric Adhesions.—Dr. John F. Erdmann read this paper. (See page 93.)

The Appendix.—Dr. John A. Bodine read this paper. He said that pain was most prominently connected with acute infections of the appendix, while digestive disturbances were more especially associated with the chronic phase of the disease. Sudden severe pain was the invariable symptom of acute appendicitis, but it was likewise a symptom of all acute abdominal lesions; therefore, its presence alone was of no diagnostic value. There should be considered the location, the quantity, and the quality of the pain. In any sudden abdominal pain appendicitis should be suspected. If characteristic, the first manifestation of pain was in the umbilical or epigastric region; later it was localized over the situation of the appendix, in the pelvis, right iliac fossa, or under the liver. It was always cramp-like and colicky, recurring at short, irregular intervals. It was to this primary pain the wave-like colicky attributes must be appended, because the succeeding or secondary pain was entirely different; this was the steady, deep ache of established inflammation and subjectively located by the patient at the nearest surface point overlying the inflamed appendix. In addition to this secondary pain, a reflected pain along any somatic nerve that lay adjacent to the organ might exist. A clear knowledge of this preferred pain not only elucidated diagnosis but accurately defined to the surgeon beforehand the position of the appendix. A profitable way to study abdominal pain and its symptomatic significance was through an anatomical knowledge of the nerves expressing the phenomenon, with an appreciation of the physiology of "referred" pain. Pain *per se* was an elusive, subjective quantity, while pain "referred" was objective and rested upon a hard-and-fast anatomical basis. Each abdominal organ possessed a sensory nerve supply from one or more of the great sympathetic plexuses which, in turn, were connected with the spinal cord. Pain impulse originating in an organ which was inflamed, was sent by this means to the cord, and this same impulse was carried efferently through whatever somatic nerves arose from that segment of the cord, and pain as a resultant was expressed at the terminal distribution of these nerves in the skin. Hence, an essential attribute of this "referred" pain was its superficial location, the area being simply hyperalgesic, and not elicited by deep pressure, but by pinching or stroking the skin. If then this phenomenon of "referred" pain was present it became a matter of thorough knowledge of the somatic nerves supplying this area to trace backwards to the segment of cord from which they originated and to follow the sympathetic nerves from the same segment of cord to the deep-seated organ at fault. The "referred" pain at the umbilicus in appendicitis lost any positive diagnostic value for the reason that the superior mesenteric plexus referred pain to the same region from the whole digestive tract below the duodenum, including kidneys and spleen, mesentery and omentum, but excluding descending colon, sigmoid, and rectum; negatively, however, it became of great importance. Murphy had lately attached a diagnostic importance to this pain far superior to any of its qualifying attributes mentioned. It rested in the position of the pain in an orderly sequence of the four cardinal symptoms of acute appendicitis: (1) pain, sudden and severe, followed by (2) nausea and vomiting, (3) abdominal tenderness accentuated on the right side, (4) elevation of temperature. These cardinal symptoms, occurring in this sequence, made the diagnosis of acute appendicitis almost positive, while the same symptoms appearing in a disorderly army negatived the diagnosis with equal certainty. The normal subsidence of pain in acute appendicitis was gradual and not sudden. The sudden cessation of pain on the second or third day of the disease was usually the beginning of the end of the patient rather than the end of the disease. In the presence of profound septic peritonitis operation was resorted to as a last chance; if careful and prolonged auscultation showed no boborygmi the operation was useless and should be refused. An operation here would discredit the only remedy which, when properly and timely applied in this disease, could save ninety-eight or ninety-nine out of a hundred. The interrelation between appendicitis and digestive disturbances became a broad one when the chronic phase of the disease was considered; but here the appendix stood convicted unqualifiedly as the etiological culprit. To epitomize he said that a patient with some tenderness in the right iliac region, with malaise, headache, furred tongue, nausea, bowel distention or fermentation, constipation or diarrhea, with or without an antecedent attack of appendicitis, in whom medical treatment failed to cure, should have a consultation as to the advisability of removing the appendix.

The Lower Intestine.—Dr. James P. Tuttle said that pain was one of the most uncertain and unreliable symptoms with which one had to deal. Pain in diseases of the large intestine was never a pathognomonic symptom but should be judged of by its character, its site, its association, and the individual in whom it occurred. Pain in the abdomen derived significance largely from the individual in whom it occurred and its own character. Hyperesthetic, neurotic, rheumatic, gouty, hysterical individuals might have pains in the abdomen as anywhere else, with little or no significance; while in persons of phlegmatic nature, with good general health, the presence of abdominal pain was always to be looked upon seriously, especially if it was associated with chill, fever, and rapid pulse, or if it was dull and persistent with associated anemia and loss of flesh. As a rule acute colic in a healthy individual was very significant, but if it occurred in sufferers from chronic mucous colitis it was never looked upon with seriousness. In patients with symptoms of beginning locomotor ataxia, acute paroxysms of pain along the colon were not dangerous but were significant from a diagnostic point of view. The conditions in the large intestine which occasioned pain were as follows: Acute colitis, pain sharp, griping; chronic colitis, pain rarely severe, accompanied with a feeling of distention and discomfort; enteroptosis, pain dragging with sense of fullness in pelvis; inguinal hernia, neuralgic, aching pain, shooting down leg and scrotum; impactions, dull aching at first, transformed into acute tenesmus and griping; acute flexure or volvulus, pain acute, griping at first, later a persistent dull aching at the point of the trouble, with periods of acute radiating tenesmus; ulcerations might give rise to no pain at all, but if present it was usually griping in character; strictures, no pain at all at first but as the caliber narrowed and the walls thickened, griping tenesmus and distention increased until actual obstruction occurred with all its category of intense general abdominal pain, nausea, etc.; neoplasms, slight nagging or griping pain with diarrhea at first, followed by dragging and lancinating pains with increasing constipation, change in the complexion, and loss of flesh. Abdominal pain from pure mental conditions did exist, but was comparatively rare. Enthusiastic specialists had found in practice and the literature a few cases of reflex pains in the abdomen or elsewhere associated with rectal disease, and had generalized so widely that one would imagine from their writings that the presence of a fissure, piles, or rectal ulcer would account for all the pains a patient could have. Occasionally one did see abdominal and remote

pains relieved by operation on the rectum, but more often they remained the same. One should exercise great care and conservatism in promising relief of abdominal or other pains by any operation on the rectum. Abscess of the suprapubic space did produce abdominal suprapubic pain. Retrorectal abscess did the same, though usually in the inguinal or hypochondriac region, owing to the direction of the lymphatic channels in this area. Distention and abdominal pain might result from reflex functional disturbances in rectal diseases, and they might also come from stricture, neoplasm, or other forms of occlusion of the alimentary tract. Simple fissure might sometimes cause abdominal pains, reflexly or by sheer exhaustion of the patient with development of a nervous sensibility in the intestines which made the simplest peristalsis painful, not so much in itself as in the suggestion of the necessity for a stool which in such cases caused agony. These cases, however, were rare and so also were the cases in which piles produced any true abdominal pain. He summed up by saying that pain in diseases of the large intestine was never a pathognomonic symptom but should be judged of by its character, site, association, and the individual in whom it was found.

Dr. Howard Lilienthal said that Dr. Dowd expressed the attitude of the medical profession when he stated that cancer of the stomach was accepted as a surgical disease in theory but was rejected in practice. He believed that Dr. Dowd might have gone even further and said that when the disease had progressed so far that few surgeons would operate then the medical man came to the opinion that it was a surgical disease. That was the wrong time to form such an opinion. Indigestion was becoming more and more a vague term, and any physician who made such a diagnosis without very careful examination was either ignorant or not conscientious. When so-called indigestion persisted in spite of the use of the ordinary remedies it was time to call in a consultant. Most gastrologists made such fine diagnoses that it was sometimes too late in the malignant disease before the surgeon got it for good to come from operative work. In simple exploratory work, if silver wire sutures were used he found that patients could get from bed within forty-eight hours. It was not a grave or serious operation. Dr. Lilienthal called attention to the hopelessness of cancer of the cardiac end of the stomach, and he expressed the hope that surgery in this region would become more successful. He referred to the use of the air chamber, the head of the patient remaining without it, while the body and the operating field, with the operator and assistants, were within, so preventing collapse of the lungs when the chest was opened. Gall-bladder troubles were often mistaken for malignant disease. Out of a great many cases that he had operated upon (86 in which the gall-bladder was removed primarily and many more in which the palliative operation had been performed before the radical one) fully 75 per cent. of those cases had been treated for months and months, and even years, for malignant trouble before the proper diagnosis had been made. The dangers of gall-bladder disease could not be overestimated. With regard to pancreatic disease he said that we were now in the beginning of the study of diseases of this organ. He recollected six cases that he had had, five being very acute, two of which he saved. The sixth case was one of carcinoma, which he operated upon, removing a small piece for examination; in this case there was an intermittent obstruction. In none of the acute cases was there any glycosuria and the diagnosis was made only by guess. Fat necrosis was present in all. He had seen patients suffer terrible anti- and post-operatice pains from adhesions. The simulation of pneumonia by appendicitis was to him interesting. One year ago he saw a child who had been seen by many eminent medical men. The family physician said the child had some abdominal condition, probably an intussusception, but the other gentlemen thought the child was suffering from some intrathoracic disease, probably a pneumonia. Dr. Lilienthal asked for operation but this was refused. The child died from appendicitis, and general peritonitis. Dr. Lilienthal spoke of the insensitiveness of the large intestine as shown early in his operative experience in doing a colostomy. The arteries of the mesocolon were practically insensitive.

Dr. George E. Brewer believed that the surgical treatment of the digestive organs would gain ground from now on. Practically all disorders of the digestive organs a few years ago were thought to belong to the general practitioner. He spoke of the great controversy regarding the medical *versus* surgical treatment of appendicitis, and said that the study of the pathology at the time of operation had convinced the medical men, so that to-day there were exceedingly few who held that appendicitis should be treated medically. The same position was held regarding the treatment of gall-bladder disease; but with increased knowledge of the pathology, the greater research, etc., the unanimous conclusion was reached that, in the majority of these cases, the diseases were better treated surgically than medically. The results that followed surgery of the gall-bladder were far in advance of those that followed the medical treatment. Again, in diseases of the stomach to-day the same position was held as was held regarding diseases of the gall-bladder a few years ago, and of appendicitis before that. With regard to cancer of the stomach there was absolutely no difference of opinion among medical men and surgeons. A patient with cancer of the stomach, if left alone, would live from thirteen to eighteen months; surgery could give far better results than that. Kocher, for instance, in 98 radical operations saved 12 per cent. more than could be saved by medical treatment. Mayo got 25 per cent. of recoveries, *i.e.* cases in which life was prolonged over three years after operation. The only thing that would save life in cancer of the stomach was an early operation. A palpable tumor was an indication that the case had gone beyond the chance for surgical cure. The presence of an obstinate dyspepsia in an individual of the cancer age that could not be relieved by the ordinary methods of treatment, would cause grave suspicion of cancer, and that patient should be treated with such possibility in view. The only way to make a satisfactory diagnosis was by exploratory incision. Ulcer of the stomach he believed to be one of the fruitful causes of chronic dyspepsia, the most of any lesion in the abdominal cavity. Unquestionably it was present in from 5 per cent. to 20 per cent. of all dyspepsias. In a large number of instances ulcer of the stomach was not diagnosed.

Dr. Max Einhorn demonstrated a method for determining the functional condition of the digestive tract. He referred to the work of Smit of Dresden, who examined the stools of patients after they had eaten the test diet, consisting of milk, eggs, meat, and starchy foods. Such a diet had to be given three or four days and then examination of the stools was made, both microscopically and chemically; such testing was very difficult, so Dr. Einhorn had devised another method. Instead of giving a certain diet and examining the stools, he attached the food stuff to little beads in such a manner that it could not get off. The patient was given such a bead with its attached food stuff and afterwards the beads were obtained from the stools and it could be learned if the food stuff had been digested or not.

Dr. Dowd closed the discussion. He emphasized the point that cancer of the stomach was primarily a surgical disease, *i. e.* the surgeon got better results than could be gotten from any form of medical treatment.

Action of the Comitia Minora.—The Comitia recommended that the president be empowered to appoint a committee of three to revise the by-laws of the Medical Society of the County of New York to conform to those of the Medical Society of the State of New York, as required by law, proposed changes to be sent to each member before the meeting in January, 1906, at which meeting they would be presented for adoption. This was

put in the form of a motion, was duly seconded and carried.

House of Delegates.—A report of the transactions of the House of Delegates was submitted to the County Society. This report appeared in the MEDICAL RECORD December 23, 1905, page 1023.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, Held in Kansas City, Mo., December 28 and 29, 1905.

PRESIDENT DR. H. D. NILES, SALT LAKE CITY, UTAH.

The Transvesical Operation for the Relief of Prostatism in the Aged.—Dr. CHARLES E. BOWERS of Wichita, Kansas, read a paper on this subject. He stated that more conservative and rational operations would yield better results and lower the mortality percentage. An exact diagnosis in many cases could be made only upon suprapubic exposure of the vesical outlet. The suprapubic operation could be done with greater exactness and would yield better results than the infrapubic in morbid conditions in the male, as had been the case in the female pelvis. The suprapubic route was as rationally indicated for the relief of the above-named obstructive conditions at the urinary outlet as it was in vesical calculus. The perineal operation offered only 30 per cent. of cures, with a mortality of 7 per cent., and a 50 per cent. chance of having exchanged one urinary difficulty for another, and not infrequently a lesser for a greater one; while the transvesical operation entirely relieved all who survived it of their urinary trouble, if it was due to obstruction in and about the vesical outlet, except when they were carcinomatous in character, without sequelæ, and with the improved operative technique of to-day no greater mortality. The controversy that was now going on relative to perineal and suprapubic prostatectomy was only a repetition of the one waged when lithotomy was undergoing its evolution. Who to-day would cut for stone in the male bladder via the perineum? The most essential thing to-day was to bring home the facts to the profession in general. First, that prostatism was due to other causes than hypertrophy of the prostate gland. Second, that the transvesical operation for prostatism had attained a sufficient degree of perfection to be recommended to this class of pitiable sufferers, with the assurance of a cure if undertaken before the inflammatory process had reached the kidney and arrested its functional activity. Third, patients should not be submitted to catheterism in the future as they had been in the past until it was hopeless to interfere surgically.

Dr. HENRY T. BYFORD of Chicago, in speaking of the etiology of enlarged prostate, thought the condition was due to some irritation; that it could not come entirely from age alone or from the sclerotic changes which occurred with age. In some cases of enlarged prostate there was doubtless a gouty diathesis, and perhaps the treatment recommended by Fletcher in his book, of reducing the calories from 3,000 to 1,500, and perhaps dieting a little, would obviate the necessity of suprapubic prostatectomy in some cases.

Dr. JAMES E. MOORE of Minneapolis stated that twenty years or more ago he did his first prostatectomy suprapubically, and as it was done at that time it was a blind, bloody, and unsatisfactory operation. A few years ago, when perineal prostatectomy was suggested and practised so successfully, he took it up and had been advocating it ever since, always maintaining that there were certain cases that could be operated better by the suprapubic route as it was done at the present time. However, in his judgment a man was not broad gauged, he did not do the best work he could do, until he performed both operations. He believed the perineal route was the choice in the vast majority of cases and by the vast majority of surgeons.

Dr. W. W. GRANT of Denver said he had maintained for years that in the average case the perineal operation was the more desirable one. In cases in which there was pus, with hyaline and granular casts, the perineal route was indicated. The dirty cases could be better and more safely operated upon through the perineum; the clean cases by suprapubic cystotomy by the well-known modern methods.

Dr. J. W. ANDREWS of Mankato, Minn., believed that there were selected cases which should be operated upon by the transvesical route, but in the majority of instances the perineal route was the better. He had operated eleven times with one death. One of the operations was suprapubic. He found it difficult, unclean, and was unable to get good drainage. Lack of drainage was one objection to the suprapubic route. The drainage was not and could not be as good as it was through the perineum.

Dr. M. L. HARRIS of Chicago said that when one attempted to generalize from a few cases in surgery, these generalizations were always wrong. The essayist had generalized from 12 cases that the suprapubic route was the only one to be done, consequently he thought he was wrong. There were many cases in which a good and thorough operation could not be done suprapubically. There were also many cases in which the best operation could only be done suprapubically; consequently the surgeon must select the best operation for the particular case. Every case of prostatism should be accurately diagnosed before an attempt was made to select the method of operation, and the surgeon could make such a diagnosis only when he employed all the means at his command, and one of these was a thorough cystoscopic examination.

Some Observations on Renal Surgery.—Dr. D. W. BASHAM of Wichita, Kansas, in this paper dealt with certain questions concerning nephroptosis and features of suppurative diseases of the kidney, and pointed out the reasons why nephrorrhaphy sometimes failed to relieve the symptoms. He discussed the desiderata necessary to make the operation a curative one. He criticised the methods in vogue, and referred to the modifications necessary to make the operation a curative procedure by fixing the kidney in a natural position and obliterating the enormous pouch resulting from the mobility of the kidney. After discussing suppurative diseases of the kidney, and referring to the principal diagnostic points, operative intervention, sequelæ, etc., he reported four cases. The methods of Jacobson and Edebohls gave permanent results, so far as anchoring was concerned, but he thought the kidney was fixed too low in the loin, too far from the center of the vertebral column, and too near the anterior wall of the abdomen. There were many operations which anchored the kidney permanently, but which were open to objection from the standpoint that the organ was not held in the natural position. Surgeons did too many nephropexies without making a thorough and painstaking effort to ascertain the conditions of the kidney, its pelvis, and the upper part of the ureter.

Dr. A. W. ABBOTT, of Minneapolis said that in a series of over 2,000 examinations, only a very small number of kidneys could be felt beyond the limits described in textbooks, but this was not in accord with clinical experience. There were very few of these patients who presented any symptoms referable to the position of the kidney, largely due to the fact, he thought, that the upper part of the ureter fell with the falling of the kidney.

Dr. WILLIAM JEPSON of Sioux City, Iowa, said there existed undoubtedly a range of mobility of nearly an inch to every normal kidney, or rather a kidney that was normally placed. He believed that each case of movable kidney had to be considered by itself. A certain number of them had to be fixed. The author was not a firm believer in decapsulation of the kidney.

Dr. C. W. OVIATT of Oshkosh, Wis., said occasionally it was necessary to operate in cases of movable kidney. If an operation was undertaken, it seemed to him that

surgeons should profit by the teaching of Harris, promulgated several years ago, and obliterate the space beneath the kidney rather than try to suspend the kidney alone by either the fibrous or fatty capsule. If one simply suspended it, undoubtedly there would be a recurrence of the displacement. The space beneath the organ should be obliterated by the Harris purse-string operation, making a new pocket of peritoneum.

Dr. A. E. Benjamin of Minneapolis said he had laid down three or four rules for fixing the kidney. One was when it showed evidence of hydronephrosis due to a faulty position of the kidney, or to a faulty position or kinking of the ureter, not allowing free drainage. Another was where there was enlarged kidney, congested or dilated kidney, and where it was tender. On examining such patients one could elicit pain by palpating the kidney. Another condition was where the kidney seemed to produce obstruction of the alimentary canal, either the colon or duodenum, and accessory organs, such as the gall-bladder apparatus, the common bile duct, etc. In such cases the kidney was prolapsed, adherent down in the pelvis, and the patients were troubled with obstipation, but on putting the kidney in position and relieving the adhesions, the symptoms would partially or entirely disappear. Patients with dilated condition of the stomach and a diseased condition of the gall-bladder, when apparently due to loose kidney, were sometimes benefited if their cases were taken early.

Carcinoma of the Descending Colon.—Dr. W. W. Grant of Denver said that the rectum was the most frequent seat of intestinal cancer. The descending colon was next in order. Cancer of the stomach was more common than that of the intestines, and its progress was more rapid. Cancer of the colon was more common in man; it was not common under thirty years of age. It was primary and circumscribed. Metastasis and constriction were late occurrences. Chronic indigestion, both occasional diarrhea and mucous discharges, were suspicious symptoms. Ulceration was of late occurrence. Floating kidney and membranous colitis might exist a long time without producing marked symptoms or seriously disturbing the health. It was less malignant than the same disease of the stomach or rectum. It was not painful until late. Stenosis was not attended with striking symptoms until obstruction was complete. Mild malignancy and late infection demanded radical operation. More care was necessary in examination at an early period in order to detect disease. He reported a case of long duration. Typhlotomy was followed by radical operation later.

Dr. I. B. Perkins of Denver saw a woman, 62 years of age, about three weeks ago, in whom there was a tumor in the groin in the region of the cecum. It was supposed by the physician who had charge of the case to be an appendical abscess. It was very hard. There was vomiting of fecal matter and had been for twenty-four hours. He made a long incision in the right rectus, and on examination found a hard tumor but no pus. The appendix was caught in the mass, as were also the ileocecal valve and portion of the cecum. He resected the intestine and closed the end of the colon by the use of the Connell suture, then implanted the ileum into the upper portion of the wound. The patient did well except that there was a slight leakage at the outer and upper portion of the anastomosis, and there was a very small fecal fistula which he thought would close soon. He thought another time he would close the ends of both guts and make a lateral anastomosis.

Dr. A. W. Abbott of Minneapolis called attention to one feature connected with cancer. He had seen two cases of intussusception in his own practice and one in the practice of the late Dr. Dunn. He thought intussusception occurred more often in cancer of the large intestine than in that of the small. He had never seen a case in the small intestine, but he had no doubt it might occur. He thought it was wrong to make an immediate anastomosis in these cases; they were the ones in which a colostomy should first be made, because the condition about the cancerous area was such that the parts would not unite if one attempted ot sew them.

Dr. J. E. Summers of Omaha, in speaking of the location of carcinoma of the large intestine, said he had found it everywhere in the large intestine, except at the hepatic flexure. In dealing with carcinoma of the transverse colon it was necessary to manipulate the gastrocolic omentum. Unless this was done with the greatest gentleness one was apt to have a complication following the operation which might be serious, namely, hemorrhage into the stomach. A week ago he removed the transverse colon for carcinoma, and as a result of manipulation there was a serious hemorrhage from the stomach for several days. His attention was first directed to this complication some years ago after an operation for incarcerated umbilical hernia, in which it was necessary to remove considerable portions of the omentum, and the manipulations had been very rough. The operation was terminated without any special difficulty, but it was followed in two hours by profuse hemorrhage from the stomach, from which the patient died.

Dr. Grant, in closing the discussion, said he wanted to urge one point, namely, the symptoms of this disease were not pronounced at an early period; but when there were suspicious indications it was very important to use more care in examining these patients than the surgeon was accustomed to do. Under favorable conditions, when the bowels were thoroughly evacuated, the surgeon might discover the presence of a growth in the colon, and this was the time when operation brought about such satisfactory results, and also was the period when the operation could be completed at one sitting.

The Choice of Ligature and Suture Material in the Surgery of the Peritoneum.—Dr. H. G. Wetherill of Denver said he would no longer use non-absorbable ligature or suture material for purely serous surfaces. The absolute sterilization of catgut was no longer difficult, and it was now realized that so-called catgut infections usually had their origin in a contamination of the gut through handling or in allowing it to come in contact with unclean surfaces or substances in or about the wound. Then, too, the chromicizing process prolonged the life of even the smaller strands to any desired time, providing the mucous surfaces or secretions were not in contact with it. These features made of catgut an ideal suture and ligature material for intraperitoneal use, and all that became necessary was the exercise of due care and skill in the selection of the catgut and the application of sutures and ligatures and the making of knots. So far he had had the good fortune never to have had a secondary hemorrhage or other accident from the use of catgut, either in the way of a slipping knot or a too rapid absorption, and he believed this immunity from accident to have been due to the exercise of extreme care in its application. For about three years he had had great satisfaction in the use of the Downes electrothermic cautery clamp in selected cases, thus doing away with all ligature and suture materials around pedicles. For vaginal hysterectomy, particularly in cancer of the uterus, it was ideal. It promoted rapidity and safety in the work, and without doubt gave much greater security against the danger of recurrences in early cases. There was in his experience and judgment no doubt that patients operated upon with the Downes clamp by either the vaginal or abdominal routes had smoother and more rapid recoveries, and above all a very noticeable freedom from the intense pain and backache so common after all pelvic operations when the terminal nerves of this region were left for days or weeks in the bight of a securely tied ligature or closely applied suture. He had had one or two experiences with the Downes clamp, however, which led him to believe that there was increased danger from thrombosis and embolism after its use, occasionally occurring several weeks after opera-

tion, and until this doubt was settled he should be most careful in the selection of the cases upon which it was used.

A New Technique for Breast Amputation.—Dr. Jabez N. Jackson of Kansas City, Mo., described a new technique for use in radical operation for carcinoma of the breast. The method of operation was devised by him about eight months ago, and had since been used exclusively in all cases of this character with which he had had to deal. From his experience, although limited to eight cases, he believed that the method had certain elements of advantage, as well as originality, that justified him in presenting it for a wider field of service. After describing the method at considerable length, he emphasized the following advantages: (1) The flap formed a covering for the chest defect, as a rule, without any tension, and thus almost entirely obviated the necessity of grafting, so frequent in other methods. (2) The drawing of the skin up to the arm did away with the fossa axillaris, and thus with a large space which nature would have to obliterate by the formation of a scar tissue, with the resultant pressure upon the axillary vessels and nerves. (3) The ligation of all vessels at their nearest point of origin did away with the use of a large number of hemostatic forceps, which caused loss of time, to say nothing of the inconvenience of having a large number of instruments in one's way. (4) The most noticeable feature to the onlooker was the marked absence of hemorrhage, so that it could almost be called a bloodless operation. (5) The entire technical portion of the operation was completed before the chest was exposed by the removal of the breast; therefore, long exposure of an enormous area of raw chest surface, with the attendant shock, was done away with. As soon as the breast was removed the operator was ready to close the wound.

Dr. Charles A. Powers of Denver said the key to the operation described by the essayist lay in the flap which covered the large skin defect, and as such it appealed to him. He asked Dr. Jackson whether in any of the cases there had been any sloughing at the corners of the quadrilateral flap. Personally, he had been very much pleased with the procedure of Dr. J. Collins Warren, of bringing up a flap from the arm. The technique of Dr. Jackson's operation was easier, he thought, and he would certainly employ this method in the future.

Dr. Jackson, in replying to Dr. Powers, said that in some instances there had been slight sloughing at the corners of the flap. In recent cases by using a wide Halsted mattress suture for tension he got union without sloughing.

Fractures About the Elbow Joint.—Dr. W. D. Haines of Cincinnati said that the open method of treatment was to be commended in all cases of extensive joint involvement. After freely exploiting the joint cavity, freeing it from clot, removing detached spicula, and fixing the fractured fragments, a strip of fascia from the arm might be inserted between the joint surfaces after the method of Murphy in excision or the Mosetig bone filling might be used, with a view to preventing adhesions until sufficient repair had taken place to permit of passive motion. The operation was completed by suturing the capsule, fascia, nerves, and skin with ample provision for drainage. The arm should be dressed in the fully extended position, placed on an incline, and a light weight applied. This position and dressing should be changed at the end of one week. After light massage the arm was redressed at a slight angle and permitted to remain for four or five days, when it was changed to as nearly a right angle as possible without paining the patient too severely. Subsequent treatment consisted of massage and passive motion every third day for a period of three weeks. Local pain and tenderness were given precedence over crepitus by the author in the diagnosis. The use of weights to overcome muscular rigidity permitted of infiltration, diminished elasticity, and interfered rather than assisted in the reduction of these fractures. The proper treatment of pain and swelling accompanying fracture was by early reduction and the application of extension, ice, or other adjuvants deemed advisable. Immediate amputation was reserved for those extensive crushing injuries, such as bumper wounds, in which the circulation and joint were so badly damaged as to be beyond all hope of repair. The author expressed the opinion that fractures about the elbow joint had been overtreated in the past.

Talipes Calcaneus.—Dr. A. F. Jonas of Omaha described a plastic operation for the permanent relief of cicatricial talipes calcaneus.

Tuberculous Peritonitis.—Dr. T. E. Potter of St. Joseph, Mo., spoke of the etiology, symptoms, and diagnosis of tuberculous peritonitis, giving the more modern views on the subject. An early diagnosis was highly recommended and the physician was urged to be on the alert when there were any symptoms pointing to tuberculous peritonitis. The success in treatment at any age was much greater when the disease was recognized before it had made too extensive progress. In the treatment the writer gave preference to surgical methods, showing that at least 66 1-3 per cent. or more recovered in the hands of surgeons, while not more than 33 1-3 per cent. recovered after medical treatment by the latest and most approved methods of hygiene and the administration of medicine. A discussion of the theories as to the benefit of surgical interference was taken up in the paper.

Treatment of Varicose Veins.—Dr. C. H. Mayo of Rochester, Minn., said that the various operations in use at the present time were necessary because of the diverse conditions and symptoms manifested by the disease. The condition was probably the result of a defect in the vein walls, valves, or enervation. The Trendelenburg operation was deservedly popular, especially for cases of vicious venous circle of the deep and superficial vein of the thigh. Enucleation of the veins in a subcutaneous manner through several short incisions was a satisfactory treatment in the majority of cases. The subcutaneous removal of the internal saphenous from above at the side of and below the knee, by destroying the main superficial channel and deep communicating branches, was the best method, accomplishing in one operation all that could be obtained by either the Trendelenburg above or the Schede below. Goerlich's report showed 84 per cent. of operations as satisfactory and 16 per cent. failures. From experience in 184 cases this seemed a fair statement of the late results from the various methods employed at present, except in the percentage of failures. Sixteen per cent. was too high, as many of those not satisfactory were much improved over their former condition.

Undescended Testicle.—Dr. A. E. Benjamin of Minneapolis said that the cause of undescended testicle might be improper development of the organ, a rudimentary vaginal process, peritoneal adhesions between the testicle and bladder or intestine, or obstruction of the canal. The testicle might be found anywhere along its course of descent to a point just outside the external ring. Hernia was a common complication of this condition. The organ would not develop as well when located at any point above the scrotum. The possible sterility of the cryptorchid, and the frequency of malignant tuberculous and traumatic disturbances, complicating this condition, all argued for an early operation to place the gland in its proper location. The operation for undescended testicle had been perfected in the last few years. It had been demonstrated that by careful dissection and an occasional sacrifice of the spermatic vessels the organs would remain in the scrotum.

The Free Interval in Meningeal Hemorrhage.—Dr. F. Gregory Connell of Salida, Col., reported two cases, one of which was quite usual, with an interval of two hours, in which recovery followed operation. The other was one in which the patient retired for the night, five hours after a slight trauma, and was found dead in the morning.

Autopsy revealed a fracture, with a large extradural clot from the lateral sinus. This second case was not very rare; yet in eighty cases collected by the writer only two similar instances were encountered. The free interval was defined as a practically symptomless period of consciousness, which followed a primary, transitory unconsciousness, and preceded a secondary, increasing and permanent loss of consciousness. This condition was usually found in association with a head injury. The cause of the bleeding was usually traumatism, with or without fracture. Various causes of the free interval were considered, with preference given to Kocher's explanation. The length of the free interval was studied, in an analysis of the 80 cases, the average length being 35 hours. The difference between extra- and intradural hemorrhages was noted, and the long free interval in this series of cases was found to accompany the intradural hemorrhage. But it was stated that much stress could not be placed upon the length of the interval as a guide to the location of the hemorrhage. The typical train of events in a meningeal hemorrhage was (1) trauma; (2) concussion, unconsciousness; (3) consciousness, free interval; (4) compression, unconsciousness; but this might be variously modified. In the diagnosis the focal signs were of more value than evidence of injury. The occurrence of collateral hemiplegia must be remembered. Fractures of limbs, previous paralysis, or congenital attachment of the iris had caused confusion in diagnosis. Contusion or laceration of the brain, abscess, fat embolism, and other conditions might closely resemble meningeal hemorrhage. In the 80 collected cases, 52 were operated upon and 28 were not. After operation there were 39 recoveries and 13 deaths. Without operative interferences, 4 recovered and 24 died.

(*To be continued.*)

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Eighteenth Annual Meeting, Held in Louisville, Ky., December 12, 13, and 14, 1905.

(*Concluded from page 38.*)

The Surgical Treatment of Floating Kidney; Post-operative Results.—Dr. Floyd W. McRae of Atlanta, Ga., argued for surgical intervention rather than attempted support by bandages or corsets, but urged careful selection of cases for operation and the recognition and correction of associated pathological conditions. Especial attention was called to the frequent coincidence of floating kidney and chronic or recurring appendicitis. The author described a new muscle-splitting operation, delivery of the kidney, partial decapsulation, the making of a broad quadrilateral suspensory ligament by dissecting forward the fibrous capsule from near the hilum to beyond the convex border of the kidney. A mattress suture was put in each angle of the capsule, near the hilum, from which the suspensory ligament had been dissected, and including the reflected flap from either pole of the kidney. These sutures were passed deeply into the muscles of the back, high up, so as to bring the kidney well into the hollow of the loin and close up to the twelfth rib. The quadrilateral suspensory ligament was next brought up between the separated muscles and held there by two silkworm gut sutures passed through all the structures from within out. A cigarette drain was placed between these sutures, and the remainder of the wound closed in layers with interrupted catgut sutures. Care was taken to avoid injury to the iliohypogastric and ilioinguinal nerves. The operation was illustrated by drawings. Twenty-two cases were reported.

Chronic Endocervicitis: A New Method of Treatment with New Instruments.—Dr. Daniel H. Craig of Boston said that the diagnosis was made to depend upon the condition of contraction or relaxation of the internal os. If, with an ordinary Simpson or Sims uterine sound, distinct resistance was encountered at the internal os, in the absence of flexion, the inflammation was confined to the tissues external to the internal os. If, on the other hand, the internal os was distinguished with difficulty or not at all, because of its relaxation and wide caliber, the inflammation was above the internal os, which was thus widely dilated to favor free drainage and to guard against back pressure. Treatment by Craig's method should be strictly confined to those cases in which the internal os was distinctly contracted. The author's treatment, or operation, consisted in curetting the cervical canal up to but not beyond the internal os with a specially designed curette after dilatation of the external os with a conical dilator, also specially designed for this purpose. The operation was quickly and easily performed at the office of the gynecologist without the use of anesthesia, except occasionally a few crystals of cocaine at the external os, and without confinement to bed. The pain, when done without cocaine, was about the same as that due to the filling of teeth. Inasmuch as the most rigid asepsis was requisite to render such ambulatory treatment safe, the outhor did not offer this little operation for the use of those not thoroughly familiar with surgical and gynecological manipulations, but for those who were able to establish and maintain a rigid asepsis. The preparatory and after-treatment consisted of three 1:5,000 formalin douches daily for three days before, and for ten days after, the operation, with avoidance of unusual exertion and abstinence from sexual relations. The cure was prompt and complete, only a relatively very few severe cases having required more than the original curettage. Tubo-ovaritis or other concomitant disease, which might be aggravated or lead to a recurrence, constituted a contraindication to treatment, except as an immediate preliminary to radical operation. The treatment was not intended as a substitute for tracheloplasty, nor for uterine curettage in cases in which the disease had invaded the corporeal endometrium. The use of the author's method should not be attempted until the original paper had been read in detail.

Fracture-Dislocation of the Condyles of the Femur with Backward Luxatien of the Leg.— Dr. George S. Brown of Birmingham, Ala., reported a case in which he did an open operation seven months after the receipt of the injury. He resorted to subperiosteal resection of the fragments with reduction and wiring, which resulted in the cure of a bad deformity, and the limb of the patient was now normal except for half an inch of shortening. The patient, aged 14, was injured in a football game at a small college, and was treated for three months for sprained knee. A skiagraph revealed fracture-dislocation of the condyles. He walked for four months after this with bad valgus and flexion of the leg on the thigh before submitting to an operation. The limb and knee joint were restored to normal. There was bony union of the fragments in their dislocated position. Through a four-inch incision down the inner aspect of the femur, the lower end of which stopped short of the level of the knee joint, the periosteum was cut through and pushed downward, the line of union chiseled through, the broken surfaces resected, and the leg brought forward on the htigh without opening the joint. The fragments were wired and the internal lateral ligament was closed with kangaroo tendon. The skin was closed with a subcuticular suture of silkworm gut. Owing to the first dressing being left too long, there was a superficial infection which did not interfere with the final good result.

Appendicitis.—Dr. W. P. Carr of Washington, D. C., said that no disease presented more varieties and more grades of severity than appendicitis. There were all shades between a mild catarrhal attack and a severe gangrenous case with diffuse peritonitis. It was apparent that no one method of operating would suit all cases. Surgeons must modify the technique to suit the case and the strength of the patient. In his first one hundred cases he had eight deaths. In his last seventy-two cases he had had but two deaths, and he believed the improvement in mortality was

due to a fuller knowledge of the condition of the patients and a suitable adjustment of the technique to those conditions. For practical purposes he divided all cases of appendicitis into four classes: (1) Unruptured, uncomplicated. (2) Unruptured, complicated by other serious disease, such as nephritis, tuberculosis, or myocarditis. (3) Perforated or ruptured—first thirty-six hours; patient in good general condition. (4) Perforated or ruptured—after thirty-six hours; complicated by diffuse peritonitis or by asthenia from long illness, or by other serious disease; patient in bad general condition. Each class was discussed at considerable length. As to the incision, it should always be either the gridiron or through the rectus muscle; otherwise hernia was very liable to follow. There was but one objection to the gridiron incision, namely, it could not be greatly enlarged without cutting across the fibers of the internal oblique and transversalis muscles. This, he thought, should never be done. It was better to close the wound and open again through the rectus muscle if a very large opening became necessary. However, if this incision was well placed, it might be stretched with the fingers and a fairly large opening made through which any uncomplicated operation might be done. The stretching should never be excessive, as paralysis of the stretched muscle fibers might result, and hernia follow.

Neglected Appendicitis.—Dr. Charles M. Rosser of Dallas, Texas, conceded the safety of an acutely inflamed appendix while the pathology was limited to the structures of that viscus; but the serious mortality following cases not so treated justified a classification of those passing the initial stage as being neglected, whether the delay was due to indifference, ignorance, or cowardice, and whether the responsibility was upon the family, patient, or medical adviser. The safe time limit would vary with the character of the attack of inflammation, the skill of the operator, and the resistance of the individual. The author considered the question of whether to operate was settled affirmatively. While appendectomies were occasionally simple in performance, yet they were prospectively delicate, and the patient was entitled to the most skilful service available in each instance, and he thought the geographical distribution of competent surgeons was sufficiently general so that there was hardly an excuse for an emergency operation by the attending physician if he were not so equipped. He advised incision in all cases at all stages except those already moribund, and in which added insult to vitality would be immediately hazardous, and a class having reached complete adhesive protection, in which a relaxed rectal orifice indicated early rupture and discharge by that route. After incision the surgeon must decide whether to remove the appendix alone, to remove and drain, or whether drainage alone should be the operation of election. But as exploration could best determine an otherwise indefinite pathological progress, the patient should be given the benefit of the doubt.

Erysipelas Toxins in Sarcoma.—Dr. W. B. Coley of New York gave a brief history of the development of the method, stating that he had used the mixed toxins of erysipelas and bacillus prodigiosus since 1892. Up to the present time he had advocated the treatment practically only in cases of inoperable sarcoma, but in view of the experience thus far gained from his own cases as well as the successful cases in the hands of other surgeons, he believed it wise to use the injections in all cases after primary operation for sarcoma as a prophylactic against recurrence. In these cases, however, the dose should be much smaller, just sufficient to produce a very slight reaction, and the treatment should be continued for two or three months. He also believed it wise, in practically all cases of sarcoma of the extremities, to give the patient the benefit of a trial with the mixed toxins before sacrificing the limb by amputation. This opinion was based upon twelve cases of sarcoma of the extremities in which the treatment had been so tried, with the result that the tumor disappeared, and in eight of the twelve cases the patients were alive and well from three to six years afterward; two were well at the time of the last observation, at the end of one year; the other two were recent cases. Three of these twelve were personal cases. Eight of them were of the round-celled variety; two spindle-celled; and in two no microscopical examination was made, although amputation had been advised by prominent surgeons; five were sarcoma of the tibia; one of the fibula; two of the femur; one of the forearm; one of the humerus; one of the thigh, involving the periosteum; one of the calf of the leg. In all of these cases amputation had been seriously considered, but it seemed justifiable to give the toxins a trial before resorting to operation. As to the final results of personal cases, of 34 cases which might be fairly classed as successful, in that the tumor disappeared under the injections with the mixed toxins, the type of the neoplasm was as follows: 12 round-celled, 16 spindle-celled, 2 mixed-celled, 1 epithelioma, 3 no microscopical examination made, but the clinical appearance, together with a history of recurrence, left practically no room for doubt as to the diagnosis. The results in these cases thus far had been as follows: Four were well less than a year; 3 were well from one to two years; 3 were well from two to three years; 3 were well from three to five years; 23 were well from five to thirteen years. In five cases a recurrence took place and finally proved fatal. In one of these recurrent cases the patient had remained well for eight years; in one, three and a quarter years; in one, two and a half years; in one, seven months; in one, six months. These five cases of recurrence, the author argued, were important in that they furnished absolute proof of the correctness of the diagnosis and refuted the statements formerly often made in regard to the successful cases, namely, that there must have been an error in the diagnosis. Dr. Coley had collected 56 cases of complete or partial success obtained by other men. The results in these cases were as follows: Thirteen were observed less than one year: in 6 the tumor disappeared and the patient remained well from one to two years; in 9 the tumor disappeared and the patient remained well from two to three years; in 12 the tumor disappeared and the patient remained well from three to five years; in 9 the tumor disappeared and the patient remained well from five to eleven years; in 5 cases recurrence took place six months to two years later; two patients died during the treatment, one of pyemia due to staphylococcus infection, the other of septic absorption, the tumor being a large intraabdominal sarcoma which had completely degenerated.

Laminectomy.—Dr. R. E. Fort read a paper on this subject in which he reported a case that he had successfully operated upon, with recovery of the patient.

The following papers were read by title: "End Results in Appendicitis Work," by Edward E. Balloch of Washington, D. C.; "Two Cases of Vaginal Cesarean Section for Eclampsia," by Dr. John F. Moran of Washington, D. C.; "Cesarean Section Necessitated by Obstruction of Pelvis by Right Half of Bicornuate Uterus," by Dr. George S. Brown of Birmingham, Alabama; "Penetrating Wounds of the Abdomen, with Report of Cases; Including a Case of Traumatic Rupture of Congenital Cystic Kidney," by Dr. C. E. Caldwell of Cincinnati, Ohio; "The Vicious Circle after Gastroenterostomy," by Dr. John B. Deaver of Philadelphia, Pa.; "Some of the Uses of Pelvic Massage," by Dr. Joseph Taber Johnson of Washington, D. C.; "Recent Progress in the Surgery of the Vascular System," by Dr. Rudolph Matas of New Orleans, La.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. George H. Noble of Atlanta; *Vice-Presidents*, Drs. Stuart McGuire of Richmond and E. Denegre Martin of New Orleans; *Secretary*, Dr. W. D. Haggard of Nashville; *Treasurer*, Dr. Chas. N. Rosser of Dallas, Texas.

Baltimore was selected as the place for holding the next annual meeting.

Dr. Lachmann, a German army surgeon of fifteen years' service, resigned his post recently because the Minister of War did not repudiate certain accusations of cowardice against Jewish soldiers which had been made in the Reichstag.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PRIMARE THORAXANOMALIEN. By WILH. ALEX FREUND. 4to, 28 pages, paper, illustrated. Verlag von S. Karger, Berlin. Paper, Marks 80.

BERLINER ARZNEIVERORDNUNGEN MIT EINSCHLUSS DER PHYSIKALISCHDIÄTETISCHEN THERAPIE. By Dr. med. PAUL RECKZEH. 16mo, 227 pages, muslin. Verlag von S. Karger, Berlin. Cloth, Marks 3.

CONTRIBUTION À L'ETUDE DE LA FUNICULITE LYMPHOTOXIQUE DANS LES PAYS CHAUDS. Par le Dr. R. MENOCAL. 8vo, 28 pages, illustrated, paper. M. Ruiz y Ca., La Havane.

DAS WESEN DER PSYCHOSE AUF GRUNDLAGE MODERNER NETURWISSENSCHAFTLICHER ANSCHAUUNG. By Dr. HEINRICH STADELMANN. 8vo, 277 pages, paper. Verlag der Aerztlichen Rundschau (Otto Gmelin), München, 1905. Paper, Marks 350.

TRAITEMENT DE LA LEPRE PAR LE PALETUVIER OU MANGLIER ROUGE. Par le DR. MATIAS DUQUE. 8vo, paper. Edmond Dubois & Co., Paris.

THIRTY-SIXTH ANNUAL REPORT STATE BOARD OF HEALTH, MASSACHUSETTS. 8vo, muslin. Wright & Potter Printing Co., Boston.

CHIRURGIE OTO-RHINO-LARYNGOLOGIQUE. By GEORGES LAURENS. 8vo, 976 pages, 471 illustrations. G. Steinheil, Paris. Price 30 francs.

ZUR FRAGE DER BOR-WIRKUNGEN. Von Dr. OSCAR LIEBREICH. 4to, 51 pages, paper. August Hirschwald, Berlin.

OPERATIONS PLASTIQUES ET ANASTOMOSES DANS LE TRAITEMENT DES RETENTIONS DU REIN. Par Dr. FAXTON E. GARDNER. 8vo, 246 pages, illustrated, paper. Vogot Frères, Paris.

THE MEDICAL RECORD VISITING LIST OF PHYSICIAN'S DIARY for 1906. New Revised Edition. William Wood & Company, New York.

MEDICINAL-KALENDER. Paul B. Hoeber, 69 East Fifty-ninth Street, New York. Paper, 75 cents.

VORTRÄGE UND AUSSATZ UBER ENTWICKELUNGSMECHANIK DER ORGANISMEN. HEFT 1. DIE ENTWICKELUNGSMECHANIK, EIN NEUER ZWEIG DER BIOLOGISCHEN WISSENSCHAFT. By WILHELM ROUX. 8vo, 283 pages, illustrated, paper. Paul B. Hoeber, New York $1.25, net.

SKIASCOPY and its practical application to the study of refraction. By EDWARD JACKSON, M.D. Fourth Edition. 8vo, 120 pages, illustrated, muslin. The Herrick Book and Stationery Co., Denver, Col.

DER AERZTLICHE RATGEBER IN BILD UND WORT. By Dr. med. Fr. SIEBERT. 8vo, 1,024 pages, illustrated, muslin. Paul B. Hoeber, New York. Cloth, $6.50, net.

VERHANDLUNGEN DER DEUTSCHEN RÖNTGEN-GESELLSCHAFT, BAND I. 4to, 248 pages, illustrated, paper. Lucas Grafe & Sillem, Hamburg.

DIE KRANKHEITEN DES BECKENBINDEGEWEBES UND DES BECKENBAUCHFELLS. By A. MARTIN. 8vo, 360 pages, illustrated, paper. Verlag Von S. Karger, Berlin.

ESSENTIALS OF MATERIA MEDICA, THERAPEUTICS, AND PRESCRIPTION WRITING. By HENRY MORRIS, M.D. Seventh Edition. Thoroughly revised by W. A. BASTEDO, M.D. 12mo, 300 pages, muslin. W. B. Saunders & Co., Philadelphia. Cloth, $1.00, net.

DIFFERENTIAL DIAGNOSIS AND TREATMENT OF DISEASE. By AUGUSTUS CAILLÉ, M.D. 8vo, 867 pages, illustrated, muslin. D. Appleton & Co., New York.

X-Ray in the Treatment of Cancer.—Results in ten cases are reported by Chisholm Williams. All were superficial growths, the accuracy of diagnosis being supported by the microscopical findings. The question is often asked, says the author, "When should *x*-rays be tried?" His reply is, "as soon as the diagnosis is made," whether the case is to go to the operating table or not. After operation, directly the scar is healed or even before that time if it shows the slightest appearance of being sluggish in the healing, a nodule of the size of a pea should have immediate treatment whether in the scar or not; this requires for its proper fulfilment constant observation by the medical attendant. A weekly examination is of the utmost importance to the patient. Even healthy wounds will heal the more readily under the stimulation of *x*-rays cautiously applied and in small doses, sufficient protection to the surrounding parts being all that is necessary. This form of treatment can be applied with any degree of safety only by medicinal practitioners; some terrible results have occurred in the hands of laymen and this fact has probably deterred patients and their advisers from taking full advantage of such suitable measures. One cannot promise, except in small superficial growths, a cure, but one can almost invariably obtain a measure of alleviation.—*The Lancet.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended January 6, 1906:

THE ETIOLOGY, PROGNOSIS, AND TREATMENT OF GENERAL PARESIS.

By JOSEPH COLLINS, M.D.,

NEW YORK.

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING PHYSICIAN TO THE CITY HOSPITAL; NEUROLOGIST TO THE HOSPITAL FOR RUPTURED AND CRIPPLED, MANHATTAN STATE HOSPITAL WEST, AND THE MONTEFIORE HOME FOR CHRONIC INVALIDS.

In discussing the etiology, prognosis, and treatment of general paresis, I assume that certain facts are taken for granted: such, for instance, as that general paresis is a disease which occurs much more commonly at the present time than at any time since its recognition; that it is oftener met with in urban than in suburban communities; that the clinical delineation of general paresis has undergone a very striking change in the past quarter of a century; that the most important apparent factor in the causation of the disease is syphilitic infection, often many years anterior; that excesses of all sorts, but more especially those that induce vascular changes such as alcoholism and strife, are powerful accelerating causes of the disease; that injury to the head, both comparatively trivial and severe, is found sufficiently often in the history of patients with general paresis to justify one in concluding that trauma to the head is occasionally an exciting or accelerating cause of the disease; that there are objective symptoms which indicate almost unerringly the existence of the disease, and that these somatic signs frequently precede the mental symptoms for a very considerable length of time, and by that I mean two, three, or perhaps five years; that the disease is universally regarded as incurable and progressive, and, finally, that so far no medication has been suggested that shapes the course of the disease once the disease has become fully developed. All this being taken for granted, the discussion of the subject which I propose to make becomes comparatively simple. I have nothing new to offer concerning the etiology or the treatment of the disease, but despite this I shall venture to cite my experience in the hope that some features of it may serve to call attention to the paramount importance of the early recognition of general paresis, and to the advisability or necessity of subjecting some of the patients to vigorous medication.

In regard to the etiology of general paresis there would seem to be a remarkable unanimity of opinion existing among those who have seen and studied the disease sufficiently to entitle them to the expression of an opinion. Kraft-Ebing summarized and made statement of our knowledge of the subject at the International Medical Congress in Moscow in 1897. Syphilization and civilization, he said, cause the disease. It is probable that neither one is an adequate determining cause. In uncivilized countries where syphilis exists general paresis is unknown; when civilization comes general paresis comes also. Unfortunately, the corollary of this statement cannot be indulged in, for the civilized country in which there is no syphilis exists only in the mind of the novelist. The elements of civilization that contribute to the causation of general paresis need not be discussed. They constitute an intangible something that has developed *pari passu* with the progress of civilization, apparently, for general paresis is more frequent in each succeeding generation. We say that it is strife and worry and work without knowing that it is any of these. It may be a habit of life; it may be the food that we eat; it may be an evolutionary condition that allows a certain flora to develop in the gastrointestinal tract and so provide the initial step for the development of the disease. The work of Ford Robertson, Douglass M'Rae, John Jeffrey, and L. C. Bruce, which tends to show that the toxemia of general paresis is of gastrointestinal and bacterial origin, seems to indicate that in general paresis there is constantly an infection of the alimentary and respiratory tracts by an organism indistinguishable from the Klebs-Loeffler bacillus. Although this work has not yet been corroborated, it is of such a nature that it stands in urgent need of corroboration or denial. At least it seems to me that if the above statements concerning syphilization and civilization are true, some demonstration of the absolute proximate cause of general paresis is awaited.

So far as the clinician can contribute to the knowledge of the cause of general paresis it has, I believe, already been done, and no information can be expected from the analysis of new statistics, even though they may be very large. Despite this, in order to introduce a discussion of the causation of the disease, I have taken the last hundred cases of general paralysis that I have seen—fifty from private practice and fifty from hospital practice—and analyzed them. This comparatively small number is utilized rather than all of the cases of general paresis that I have seen, first because the records of the cases are fairly complete (many of the patients having been under my observation for months at a time), and, secondly, because it seemed to me that as much and as reliable data can be gotten from a hundred cases as from five hundred. Of these 100 patients 85 were males and 15 were females. This is, perhaps, a somewhat higher percentage of females than is given by most writers, but it is to be noted particularly that only one of these fifteen was seen in private practice. So far as professions and occupations are concerned, it is difficult to find one not represented in our hundred cases. There are clergymen, physicians, jurists, statesmen, bankers, capitalists, laborers, and artisans of all sorts. In Europe the disease is rare among the clergy and common among the officers of the standing armies; but whether there is a similar social distinction here I am unable to say.

Most writers believe that heredity plays a rôle of much importance in the development of general paresis, and my statistics would seem to indicate that it does. Of the 100 cases there were no less than 23 in which there was a history in the ancestry

of organic or functional nervous disease of sufficient severity to be noted by the family of the patient. This is a far greater percentage than that of patients with other nervous and mental disease. It is in opposition, also, to the statements of such writers as Regis in France and Mendel in Germany who believe that neuropathic heredity has very little bearing on the occurrence of the disease. In France much is made of the so-called neuroarthritic heredity as a predisposing factor to general paresis, but until arthritic heredity is very closely defined or until a person who believes in it is able to state exactly what he means, so that it is intelligible to another, one cannot hope to say with much confidence how much of a rôle it plays as an etiological factor.

The following table shows the relative frequency of the commonly attributed causes of the disease: History of syphilis in 55 cases; history of syphilis denied or not obtained in 45 cases; history of injury in 9 cases; history of nervous or mental trouble in the family in 23 cases; no excesses (alcoholic or sexual), 54 cases; moderate excesses, 23 cases; great excesses, 23 cases; paretic type, 73 cases; tabetic type, 27 cases.

Duration of the disease when first examined:

Three and one-half years	1
Four years	9
Five years	6
Six years	2
Seven years	3
Twelve years	1
Unknown	10

Of these 100 patients there are, therefore, 55 who admitted, and were in a mental condition to state, that they had had syphilis. There were 7 whose collateral history made it fairly certain that they had had syphilis. Such, for instance, as a young woman whose husband had syphilis at the time of marriage; another, a man, whose wife now has tabes; another a woman who had five miscarriages in succession and one dead-born child; another whose wife had six miscarriages in succession; another woman whose husband died of general paresis; a second whose husband died of general paresis; another whose husband died of syphilitic endarteritis in my own care in the hospital, the lesions having been demonstrated after death. It is possible also to include in this list a young woman 23 years old who was married seven years and had never been pregnant, despite the fact that she came from a productive family; and another who had two miscarriages in succession in the early period of pregnancy and who had since then remained sterile. This makes a total of 62 out of 100 in which it is fairly certain that a syphilitic infection had existed. It is, perhaps, legitimate to include under the caption of those who had syphilis one who admitted promiscuous intercourse with Chinese women, another who had an attack of iritis and choroiditis and still shows the evidence of them, and a third who, while denying the primary lesion, gave a history of an erythema and periosteal pains which may have been of specific origin. This brings the number up to 65 out of the 100. This, therefore, leaves 35 patients who denied syphilis and who gave no evidences of its existence. This, I need scarcely say, is about the percentage of syphilitic history in the vast majority of statistics.

On the other hand, there were many patients seen for the first time in a more or less advanced stage of the disease who were not in a mental condition to give reliable information concerning whether they had or had not had syphilis, and among these were a number of private patients brought or sent oftentimes from a distance by their physicians, in whom, in addition to not being able to give the information themselves, it was quite impossible to make inquiry from anyone who was likely to know. In these statistics such cases are put down as unknown in reference to syphilitic infection.

The average age at which these 100 patients had syphilis was 25, and the average age when general paresis developed was 36½, i.e., about 11 years is the average period that elapses between the infection and the development of the first symptom of the disease, out of which, in my opinion, it commonly flows. It should be noted that in many cases the time between the existence of the chancre and the development of the first symptom of general paresis was very short. For instance, in case 4 the specific lesion developed at 36, the general paresis at 41; case No. 13, the chancre when 31, the first symptoms of general paresis at 34, and during the interval almost continuous vigorous antisyphilitic medication; case No. 15, specific lesion at 35, treated for a year, first symptoms of general paresis at 35; case No. 17, initial lesion when 24, homeopathic treatment, beginning of general paresis when 29; case No. 35, lesion when 19, no treatment, symptoms of general paresis when 22; case No. 65, lesion when 44, treated continuously for eighteen months, symptoms of general paresis appearing when 47; case No. 92, syphilis when 20, treated one and one-half years, symptoms of general paresis developing when 24, and several other cases in which the time between the existence of the syphilitic lesion and the development of paresis was more than seven years, so that my experience is at variance with the statements of Fournier (*Académie de Medicine*, February 28, 1905), that "general paresis is never a manifestation of recent syphilis nor of very remote syphilis. In the majority of cases it appears between the sixteenth and seventeenth year after infection." I am anxious to hear whether the experience of my colleagues is similar to my own, for I have been many times reminded during the past ten years that the interval between the infection and the development of the general paresis is becoming briefer.

There is another point in the etiology of general paresis in which, although I am not prepared to speak with any real positiveness at this time, I am inclined to think it is likewise at variance with the statement of Fournier, who says "insufficiency of treatment of the syphilitic infection is an etiological factor of great value. A small number alone of syphilitics who have been well treated become general paretics." In order to make a statement concerning this question which would entitle it to considerable weight, I should have to review my entire experience with general paresis, and this I am not ready to do now. Later, when I shall say a few words about the treatment, it will be pertinent to inquire what constitutes sufficient treatment. Many of the patients whose histories are analyzed in these statistics had vigorous antisyphilitic treatment for upward of a year; 11 of them were treated in hos-

pitals for four or five months, but many were not treated except for a few weeks after the local manifestations had disappeared. Altogether the average duration of treatment was something over seven months.

The number of patients whose history showed trauma of any sort was 9, and it is very interesting to analyze these cases, as there seems to be a disposition on the part of many of our most recent writers to deny the etiological importance of trauma. For instance, one of the best descriptions of general paresis in recent times is that of Dupré, in the *Traité de Pathologie Mentale,* by Gilbert Ballet, who states that cranial traumatism has a slight etiological influence and that two factors—syphilis and cranial traumatism—are responsible for most of the cases that seem to develop after trauma.

Case No. 2 of my series gave a history of a blow on the side of the head occurring three years before the onset of the paretic symptoms. After the blow he was unconscious for a short time and went to a hospital. He was a laborer, who denied syphilis, but who drank to excess for many years. Case No. 6, a painter, stated that he had had several falls off roofs. After some of these he was unconscious and laid up for some time. The last fall was a year or a year and a half before the symptoms of general paresis showed themselves, and consisted of a fall from a ladder to the sidewalk. He struck the back of his head and had some hemorrhage from the right ear and was unconscious for eight hours. The only way he could account for that fall was that he had an attack of vertigo. He denied syphilis, but admitted an attack of gonorrhea and an attack of swelling of the glans penis about twenty-five years before. The next case was a butcher 52 years old, who had typical manifestations of general paresis and an advanced degree of arteriosclerosis. He had had several falls from a wagon. He died from an attack of apoplexy three years after onset of his disease; no autopsy. He denied syphilis. The fourth case was a plumber, 35 years old, who had had a fall on the head four months before. The symptoms of paresis in his case were well developed. The next was a patient who had been assaulted in the street and rendered unconscious two months previous to the development of notable symptoms of the disease. When I saw him somatic signs of the disease were pronounced. The next was a young man 18 years old, who gave a history of having been hit on the head when 9. The difficulty in all these cases is to trace a relationship between the injury and the mental disease. In most cases it is more apparent than real. The majority of patients who attribute their symptoms to head injury are found, if investigated closely, to have had syphilis as well. This point is well illustrated by a patient, a man 35 years old, who one year before the development of the disease received an injury to the head, was not unconscious, but felt "numb" for a week following. The next was a patient 62 years old, who received a severe injury to the head when 20 years old. All of these denied syphilis. The next was a man 36 years old, who received a blow on the head one month previous to the time that his physician found unequal, Argyll-Robertson pupils, absent knee-jerks, slowness of speech, and forgetfulness. To his physician he denied ever having had a chancre. When I saw him eighteen months afterward I found a scar on the glans penis, and he, when confronted with this, admitted then having had syphilis eight years before.

There are a great many cases in the literature in which it is reported that the phenomena of general paresis have followed trauma of the head, some of them soon afterward, others remotely after the head injury. In some of these cases there is neither a direct history of syphilis, nor can it be assumed that syphilis existed unless hereditary.

Belonging to the latter category is a case recently reported by Marie and Violet (*Le Progrès Médical,* November 11, 1903). A boy began to have fractures of different bones in the body from injuries often trifling, often violent. The fractures reunited quickly, but recurred oftentimes in the line of previous fracture. After his death, at 38 years, the diagnosis of general paresis was confirmed. The writers look upon this case as one of hereditary syphilis, which was, most probably, the cause of the predisposition of the bones to fracture.

I see no reason for not admitting that general paresis may arise apparently from injury to the head. Whether or not there must have existed previous syphilitic infection in every case is another question; but my opinion is that it is not necessary. Cases, however, in which the somatic symptoms occur within a few months—less than six—after the injury I am inclined to look upon as the result of syphilis and trauma.

One should hesitate to say that the disease has come from injury in any given case until all the facts of the case have been very carefully examined. My own experience is that the more thoroughly one investigates the cases of general paresis that are attributed by the patient or the family to injury, the fewer become the cases that may legitimately be said are due to injury. For instance, the following case is an excellent illustration, a man, 43 years old, a driver, who is now under my observation. His wife states that three years ago he fell from a wagon that he was driving, and his present illness dates from that time. Although he fell on his side and hit the head and shoulder, it was the left elbow particularly that sustained injury. He kept at his work, but a few days afterward he noticed a weakness of the left upper extremity and complained of some pain along the outer border of the hand. Three weeks later a can of milk that he was lifting fell on his foot and broke his toe, for which he went to a hospital, where he remained for six weeks while the fracture was healing. On leaving the hospital he was unable to go back to work, because of physical weakness and because he was growing "silly." This condition continued to increase, until now he presents the typical picture of a taboparetic. Were it not for the fact that the diagnosis of tabes in a well-developed stage was made in the hospital to which he went for treatment of the injury spoken of, the case might well figure in the statistics that set forth the relation of paresis to trauma.

Alcohol has a definite relationship to the development of general paresis, but here again the question is whether or not it is in itself a competent producing cause. My opinion is that it is not. The excessive use of alcohol can cause a clinical picture resembling that of paresis, one to which the name alcoholic pseudoparesis is given, but that it can alone cause true general paresis is denied. Some alienists, such as Regis, for instance, deny that alcohol has any contributory effect. The statistics upon which my remarks are based show that of the 100 cases 23 were very excessive drinkers and 23 more were what they termed "moderate" drinkers. It is fair to assume that several, at least, of the latter used alcohol to very considerable excess. This would show that a third of my 100 cases at least had taken alcohol excessively, and probably thereby injuriously. I am inclined to agree with Magnan and Garnier, who hold that alcohol has a definite relationship to the development of general paresis.

When one approaches a discussion of the treat-

ment of general paresis he is confronted at once with the fact that it is practically universally conceded that the disease is incurable. In the literature of twenty-five or thirty years ago one finds no difficulty in turning to recorded cases of recovery, but such a statement is not true for the recent literature, and, of course, the question at once arises, Were these early cases genuine examples of general paresis, or, if they were, were they cured?

In 1870 Nass reported 7 cases of recovery. Later he made the statement that 6 of the patients had relapses and died of severe cerebral disease, and in the seventh case the diagnosis was doubtful. To be sure there is here and there in modern literature reports of cases in which the objective symptoms have been held in check and the subjective symptoms caused to disappear by the use of this or that medication. But these communications are, in a very large part, from those who have had comparatively small experience or those who have shown their willingness to publish cases as cured after too short an interval of cessation of the symptoms to justify the use of that term. I am not referring now to those who maintain that there is a preparetic state of the disease, and that if treatment is carried out vigorously during this time the disease may be prevented from developing; I am speaking only of the treatment of general paresis. During the past five years particularly there have been a number of articles and monographs written, particularly by French writers—Devay, Lemoine, Leredde, Lejeune, Marchand, and others—on the curability of tabes and general paresis by the use of mercurials in massive doses—"mercurielization intensive," as they call it. For instance, Leredde (*Revue Neurologique,* Congrès de Toulouse, 1902) is of the opinion that tabes and general paresis both are syphilitic diseases and are curable. He objects to the term "parasyphilitic," which most writers use to describe the probable pathogeny of the disease. Devay (*Lyon Médical,* February 15 and 22, 1903) says that 23 cases were modified, improved, or transformed in their clinical features by injections of calomel and the use of iodide of potassium in large doses. He divides his cases into four groups, the first group consisting of 3 cases in which there was attentuation or disappearance of the somatic signs, with very incomplete disappearance of the mental symptoms. The second group, 5 cases, in in which the individual's intelligence remained weakened, but there was great amelioration or complete disappearance of the somatic signs. A third group, of 5 cases, in which the mental signs practically disappeared, but the physical signs persisted; and the fourth group, in which there was absolute disappearance of the physical and mental symptoms. In this latter group there are 10 cases. Devay's attitude toward many of the features of general paresis is such that one who attempts to criticise his paper finds himself at a loss. For instance, he says that spontaneous remissions occur in exceptional cases of general paresis only. This would seem to show either a limited experience, or the encounter with general paresis of a different kind than that which we see, for it is a statement at variance with the experience of most physicians. Like Leredde, his conclusion is that general paresis is neither alcoholic, arthritic, nor toxic. It is syphilitic and not parasyphilitic. He thinks that energetic specific treatment should be instituted at once; it matters not even though the case is well developed. The duration of the treatment should be longer the longer the disease has been in existence. In cases of cure treatment should be maintained after recovery. He says the iodate of mercury should be given in extremely large doses, often more than ten grains. Fear of cardiac complications is ungrounded, he having noted them only in one case. In the *Archives of Neurology,* 1902, he states that he submitted 90 cases of general paresis to energetic mixed specific treatment, and that 21 of these cases were modified, improved, or temporarily cured. Lemoine (*Revue Neurologique,* July, 1902) reports six observations on general paresis in which improvement was very evident from energetic mercurial medication. He thinks it is the large dose rather than the particular salt of mercury which is efficient. Nevertheless, he prefers the benzoate because of the facility with which it can be given. He thinks that the prospects of success stands in inverse ratio to the age of the patient. He gives from two to six centigrammes of the benzoate of mercury daily, repeating these injections for fifteen or twenty successive days, and in some cases for a period twice as great, depending upon the individual's tolerance and the results obtained. The injection is then omitted for ten or fifteen days and again resumed after that time in such a way that a similar quantity is injected every other day only. In this way the injections are continued for months, and in some cases for years. Marchand (*Archives de Neurologie,* 1903) gives the mercury in the shape of intraspinal injections, believing that the manner of introducing it into the organism may exert an influence on its mode of action. After the removal of about 6 c.c of cerebrospinal fluid he injects 2 milligrammes of biniodate of mercury and 2 cg. of potassium iodide dissolved in 2 c.c. of distilled water. These injections are repeated once a week. He has not observed internal symptoms. Of 7 patients treated in this manner during three months 4 were improved.

This may be taken as a sufficient citation of the treatment that has been instituted by many in France and of the claims that are made for it. These claims have been received hostilely by a large number of well-known neurologists and alienists in France who have expressed themselves on the subject. Many of them, such as Brissand, Marie, and Dupré, have spoken very decidedly against them.

My own experience with the intensive mercurial treatment of tabes and general paresis extends now over a period of five years. During this time I have treated many patients suffering from these diseases in the way suggested above, and I am ready to state results in the cases of general paresis, but not ready to state them in the cases of tabes dorsalis. I can do this very briefly: In no instance have I seen intensive mercurialization to be of any service whatsoever in general paresis after the disease was fully developed, *i.e.* after it had the ordinary somatic and psychic signs, even though the latter were not pronounced. I have had three cases in which it seems to me the disease has been arrested in its development, not cured, because the physical signs of the disease still remain, but in one of them, now of five years' duration, and another of three years' duration, the disease has made no progress whatsoever. These three cases I shall cite briefly.

Mr. X., 44 years old, a man of affairs, unmarried, had syphilis when he was 23 years old. He was treated by a well-known syphilographer for three years and pronounced cured. The infection was considered to be a mild one. He remained well, except for some minor ailments, until he was 39 years old, when he had an attack of convulsions which was thought by the physician who saw him to be due to congestion of the brain or a rupture of some blood-vessels in the brain. As a result of this illness he was confined to his bed for a fortnight, during which time there were no evidences of paralysis. Examination of the urine made at this time gave no

indications that the attack might have been due to uremia. A few months afterward he consulted me for headache and at that time I found Argyll-Robertson pupils, absence of one knee-jerk, and a slight tremor of the hands and of the tongue. His blood-pressure on the Stanton apparatus was 135, his pulse rate 86, and the arteries not perceptibly thickened to the finger. His speech was slightly indistinct. He complained of attacks of depression without cause. I made a diagnosis of beginning general paresis and sent him to a physician for a corroboration of this diagnosis, which was given. He was then put upon mercurial treatment in the shape of hypodermics of bichloride of mercury, beginning with 1/8 grain daily, and these were rapidly increased until he was taking ½ grain at each dose. These were kept up for two months. At no time were there any marked symptoms of mercurialism. At the end of this time he was given a course of tonic hydrotherapy and small doses of iodide of potassium, *i.e.* 10 grains four times daily, and later sent away for a six months' rest. When he returned he was put upon a similar course of mercurial treatment as that mentioned above. Since that time he has had another two months' course. At the present time he seems to be in excellent mental and physical health. The only somatic sign that has disappeared is the tremor; the others remain as they were. To be sure, this patient has had symptoms of the disease only five years, but during that time the disease has not developed. Whether or not the disease has been arrested permanently cannot, I think, be said at this time. At least I may say that it is one of the first cases that I put upon the intensive mercurial treatment, and it is one that has encouraged me to adopt a similar treatment in many other cases.

The second case is that of a man whom I saw first after he had been for a short time in an institution and was discharged therefrom as a patient in a state of remission. He is now 42 years old. When he was 38 he developed symptoms of mental confusion, associated at times with some violence and at other times with depression. He had given up his occupation as a railway conductor some years before, and had latterly been engaged in the liquor business. Although he denied excessive drinking, it was thought that his symptoms were due to alcohol. He was discharged from the institution after four months' treatment. When I saw him a short time after this (now three years ago) his wife stated that he was indifferent to the family wants, that he was easily annoyed and excited, and when in such a condition he would readily lose self-control, and that he did not display the same interest in himself or in his family that he did before. Examination showed Argyll-Robertson pupils, slight tremor of the lips, tongue, and hands, and exaggerated tendon-jerks. Mental examination showed that he was capable of expressing his thoughts in writing, that his memorial recall of remote and recent events was about as good as the average individual of his age and education, that he revealed a moderately comprehensive insight into his condition, insomuch as he admitted that all that his wife stated concerning his disposition and his attitude toward her were true. His only explanation of them was that he was weak. His orientation was good, his capacity to grasp ideas and to make them the basis of intelligent observation and comment were such as to call for no remark. He had had syphilis when 24 years old, and had been treated by a regular physician for about a year, and said that he was given pills and colorless medicine "that tasted salt." From his history and from his physical signs the diagnosis of general paresis was made. He was put upon injections of the salicylate of mercury, beginning with half a grain, administered twice a week, increasing to 1½ grains, kept up for a period of six weeks, then a six months' interval was allowed to lapse, during which time he received vigorous tonic treatment, and at the end of that time he was put back upon mercurials for a period of three months. At the present day he is earning his livelihood and at the occupation which he had before he went to the sanitarium. Aside from the physical signs spoken of above, he may be considered quite normal. He took an active part in the late municipal election in this city, and gave as legitimate an account of his espousal of the Municipal Ownership Ticket as any that I have heard. He may, of course, be in a state of remission, and it may be that the mercurial treatment has not benefited him. At least I should say it is possible that he would have had as protracted a remission if he had not had mercurial treatment, but be that as it may, I intend to put him through a similar course of treatment at the end of another six months.

The third case in which intensive mercurial treatment has seemed to me of benefit is that of a young man, 32 years old, who came to me in the summer of 1903, *i.e.* two and a half years ago, with the symptoms that were considered to be indicative of "nervous prostration." He had been very active in the business and social world, and had made some success. Without attributable cause he began to worry about his financial future. He feared that he was going to lose all that he had, that he and his family would die in an almshouse. His conduct, in a measure, became based upon this conviction. He refused to put on a clean shirt more than once a week for dinner, although the drawer may have contained a dozen or more ready to wear; he would go into the dining room of a hotel and look over the bill of fare and pick out the least expensive viands. He dismissed his coachman, tried to dispose of his house, gave up a trip to Europe that had been planned, and in many other ways displayed evidences of his delusion. In addition to this he was emotional, particularly depressed; sometimes the fits of depression would last a short time, sometimes several weeks. There was no lack of insight into his own condition; he appreciated how distressing his convictions were, and could be reasoned out of them, but they would return. He still continued to go to business, but his constant attempt to curtail expenses led the other members of his firm to induce him to stay away. There were no evidences of exaltation, even when the micromania was not upon him, and no indications of his lack of capacity to grasp the complexities of the average problem presented to the ordinary individual in daily life. The only physical sign which he had was the Argyll-Robertson pupils, although the knee-jerks were fairly lively. This young man had contracted syphilis when he was 19 years old, and had never had what is considered to be adequate treatment. There was some debate whether the lesion was a true Hunterian chancre by the first physician whom he consulted, and he received no treatment at that time save local treatment. Afterward he came to this city to consult a laryngologist, who suspected that his throat lesions were due to syphilis, and put him upon biniodate of mercury and later mixed treatment. He took this treatment altogether about six months. When I took charge of him he was at once put upon injections of corrosive sublimate, the dose averaging from 1/4 to ½ a grain each day. After the first few doses he developed disagreeable dysenteric symptoms which yielded readily, however, to treatment, and after that he was able to take the sublimate very readily. This young man

remains free from subjective symptoms, but, like the other cases, his pupils are still unresponsive to light.

Those are the only cases that I have to report in which vigorous antisyphilitic medication seems to have been of real benefit. They are open to the objection that a sufficient length of time has not elapsed to justify one in saying that they have been arrested or even modified in their course. They are not, however, open to the criticism that they are not cases which would eventuate in genuine general paresis if the disease process were not checked.

I have to report the treatment of 17 other cases of general paresis in which the intensive mercurial medication was given a thorough and adequate trial, but with no results whatsoever so far as the course of the disease was concerned. None of them was encountered so early in the course of the disease as the three mentioned above.

There is not very much in this report, as you will admit, to encourage one in the belief that general paresis is a disease that may be arrested or cured by antisyphilitic medication administered after the disease has got a thorough start, and this leads me to the statement of what I consider to be the crux of the whole matter, viz., the recognition of general paresis at a much earlier period in the disease than has been commonly done heretofore. The question that I ask myself is does such a majestic disease as general paresis develop with the abruptness which it is said to do by patients and their families when they consult the neurologist, or is this disease heralded by physical, mental, and emotional symptoms which, if they could be observed, would indicate a long time in advance the overwhelming disease process that is threatening? Dana, in a paper entitled, "The Curability of Early Paresis," published about a year ago, spoke of a stage of preparesis, and maintained that it was in this period that antisyphilitic medication might permanently arrest the disease. He did not attempt, unfortunately for us, to depict the features of the disease in this preparetic stage. It may be presumed that he was deterred from so doing because of the inherent and almost insurmountable difficulty of describing what it is in the story of the preparetic and in his appearance that permits the experienced neurologist to say when in his judgment general paresis has begun. I feel that my auditors will all understand what I mean, but I am by no means certain that the general medical reader may divine my meaning. The general practitioner knows that every now and again a serious cardiopathy, manifest by tachycardia, general physical weakness without adequate or attributable cause, and symptoms of this enfeeblement, are dependent upon a slowly developing, almost an undetectible, aortic stenosis. At a stage when such symptoms as those that I have described exist neither murmur nor enlargement of the heart can be made out. Still the man experienced in diseases of the heart will recognize such symptoms and be willing to make the diagnosis at a period when an individual less experienced would hesitate if not deny such diagnosis. That which permits the specialist to make the diagnosis in such a case is summed up in the word experience, and that which permits the neurologist to make the diagnosis of general paresis in its very earliest stages is of the same quality. Unfortunately, it is not often that he is permitted to try his practised hand in making the early diagnosis, for the majority of the cases that are seen or brought to him are cases in a well-developed or in an advanced stage. That which we may legitimately ask, I believe, is that the diagnosis of neurasthenia should never be made by the general practitioner until after a routine physical examination has been made of the patient. Such examination will be productive of good in two directions; in the first place the diagnosis of neurasthenia will be made much less often, and in the second place general paresis will occasionally be recognized in its incipiency. I need not say to this audience that the slightest manifestation of loss of the pupillary light phenomenon, premonitional display of labial and facial tremor, unattributable lingual tremor, disorder of the tendon phenomenon, particularly of the lower extremities, occurring in a patient who has some one, any, or all of the symptoms of neurasthenia, should be immediately put in the category of suspected cases of general paresis, and if the suspicion is a strong one, should, I think, also be put upon vigorous antisyphilitic treatment, and especially if the patient admits that he has had syphilis, and that he did not receive vigorous and protracted treatment. I should like to say that a patient presenting such symptoms should be sent to a neurologist who will avail himself of a more extensive examination, particularly a cytological examination of the cerebrospinal fluid and of psychological tests for apperception, mental coordination, memorial recall, and other components of close and critical reasoning. Perhaps one should attempt to say more specifically what the mental and emotional phenomena of this stage of general paresis which heralds the onset, but I do not think that it can profitably be done. Even in the earlier period of the disease, when the symptoms of general paresis are well developed, the variability of the mental and the emotional phenomena is so profound that a description of these qualities of the soul is very difficult. For instance, it is commonly stated by psychiatrists that a lack of comprehensive insight concerning their condition is one of the chief mental attributes of the patient with general paresis, but I have no doubt that we all have patients with general paresis who are as keen about their disease as sufferers from some of the visceral diseases, let us say, so that loss of insight cannot be made a criterion, neither can any one of the other multiform mental manifestations of the disease. Nevertheless, this does not deter me from saying the most constant mental defect of the general paretic, in my experience, is of promptness and completeness of memory, and that therefore memory tests should be made most carefully in every suspected case.

A discussion of the prognosis of general paresis resolves itself into a discussion of the prevention of the disease, for it must be admitted that the fully developed disease will end invariably in death. Of the two sources from which it flows—syphilis, and that indefinable something that has come with progress, we, as physicians, deal only with the first. Are we doing all that we can to prevent syphilis, and are we doing all that we can to cure it? The neurologist more than the worker in any other department of medicine sees the remote and terrible devastation caused by syphilis. Committees on the "Social Evil" would have us believe that the best way of preventing syphilis is through the coercion or control of the sex that commonly disseminates it. Personally, I believe that much could be done to prevent the occurrence of the disease if colleges would require as one of the entrance requirements from their applicants not only a knowledge of academic subjects, but likewise a theoretical knowledge of the capacity for misery and suffering which an unnecessary and promiscuous sexual intercourse has. There are some natures that will always take risks, no matter how hazardous they are, but numerically they are not so great, I think, as those who are by nature conservative, and who, if properly warned, will look out for their welfare. Americans marry early in life, and no means should be spared to assure them that

pre-matrimonial continence is a factor that makes for post-matrimonial health.

The second factor in the prevention of general paresis, viz., that of adequate treatment of patients with syphilis, is one that I hesitate to discuss. I feel reasonably certain, however, that patients with syphilis are oftentimes given a positive assurance that their disease has been cured after what I consider has been an inadequate administration of mercurials. At least this statement is true if I am to rely upon what patients who have had syphilis, and who come to me for the relief of symptoms which may or may not have flown out of syphilis, tell me. My experience as a teacher in a post-graduate medical school has shown me that many physicians believe that iodide of potassium is an antisyphilitic agency in the sense that it overcomes, destroys, or interferes with the bacillus of syphilis or its products, or if this phrase is objectionable, with the virus of syphilis. The teaching that iodide of potassium is an antisyphilitic agency only in so far as it may assist in the removal of syphilitic products is not always acceptable to them.

In conclusion, I wish to say that the prognosis of general paresis stands in certain relationship to (1) the time of the diagnosis of the disease, (2) the clinical type of the disease and (3) the age of the patient. If the disease can be detected in what Dana has called the preparetic stage, there is a chance of arresting it. The type of the disease that is least influenced by any kind of treatment is that form that begins insidiously, in which there is no symptom that stands out conspicuously to attract attention, and in which the patient often keeps to his occupation until a comparatively advanced stage of the disease and finally the prognosis is worse in the young.

37 West Fifty-fourth Street.

THE THERAPEUTIC VALUE OF WARM MOIST AIR AND HOT DRY AIR IN THE TREATMENT OF DISEASES OF CHILDREN.*

By THERON WENDELL KILMER, M.D.,

[NEW YORK.

Our ancestors long ago discovered the fact that a baby with croup was greatly relieved by the use of steam generated by a teakettle. This, we may then safely say, was the first application of the therapeutic value of warm moist air in the treatment of disease.

For many years various kinds of so-called croup-kettles have been devised for the scientific application of warm moist air in the shape of steam in respiratory diseases. In some hospitals for children the attending physicians have thought so well of this remedial agent that separate rooms, called "Inhalation Rooms," have been provided in the hospitals, where plain or medicated steam is constantly being generated, so that the little patients can be placed from time to time in this warm, medicated atmosphere.

What are the diseases, then, to which infants and young children are subject, and in the treatment of which the beneficial therapeutic value of warm moist air is seen at its best?

Croup.—A child suffering from catarrhal croup, when placed in a warm, moist atmosphere, will be seen to be immediately relieved, the harsh, brassy cough, the stridulous inspiration, and the cyanotic face will all be much improved by the inhalation of either plain or medicated steam.

*Read before the West End Medical Society on November 25, 1905.

Bronchitis.—In acute bronchitis, especially if it be of the capillary variety (of the fine tubes), there is nothing like the application of steam to ameliorate the symptoms. Many an infant with bronchitis receives no other form of treatment, with a happy termination to an otherwise fatal issue. Take a baby, for instance, breathing 40 to 90 to the minute, somewhat cyanotic, chest full of dry, crackling râles, and a tight, constricted, spasmodic condition of the fine tubes of the lungs; place this child in a crib draped with a sheet or blanket, and introduce under this tent plain or creosote steam by means of a croup kettle, and note the almost immediate change in both the character and number of the respirations. Oftentimes the baby will go to sleep while being steamed and thereby get a much-needed rest. A baby with bronchitis should have these inhalations for, say, half an hour out of every two hours. He need not be disturbed to steam him. If he is asleep when steaming time arrives, simply cover his crib with a sheet or blanket and introduce the spout of the croup kettle underneath the sheet (Fig. 1).

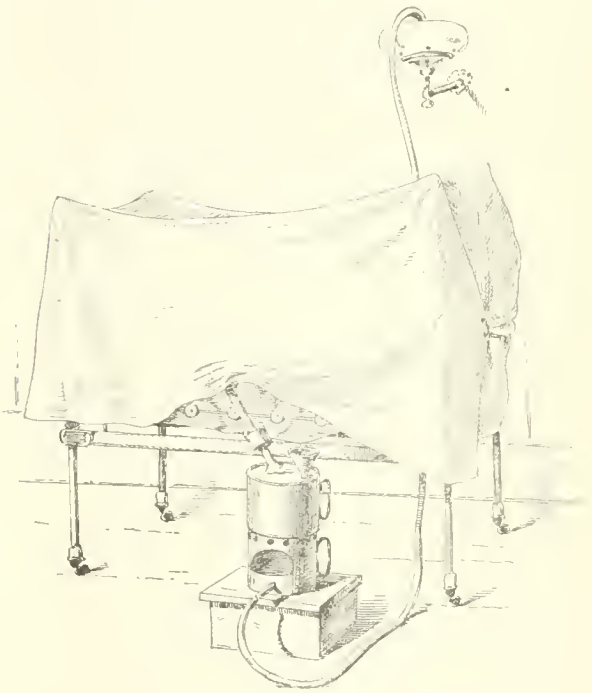

Fig. 1.—Crib draped and croup kettle in place.

In some cases, a child from one to four years old is best steamed by having it on the mother's or nurse's lap, covered by a sheet (Fig. 2). The child is often less frightened when steamed in this position.

Asthma.—Attacks of asthma, although infrequent in infants, do occur, and nothing will abort an attack or relieve the baby so quickly as steam inhalations.

Pneumonia.—In both bronchopneumonia and lobar pneumonia in babies, steam is one of our best and most used therapeutic agents, and is applied in a similar manner to that described under the head of bronchitis. Steam inhalations, the application of mustard to the chest, an occasional dose of castor oil, and proper feeding and hygiene, often constitute the only remedial agents in many cases of pneumonia in infants.

Diphtheria.—In cases of faucial or laryngeal diphtheria, we find that occasional inhalation of steam greatly relieves the congestion and dryness of the throat that usually accompanies this disease.

Laryngitis.—In cases of laryngitis seen in older children, inhalations of plain steam or vapor containing benzoin or turpentine will be found to be of great benefit.

Whooping-Cough.—Some children with whooping-cough will rest more easily if a steaming is given just prior to the child going to bed for the night. In others the paroxysms will be greatly reduced in intensity by giving the child a steaming two or three times a day. In many cases of croup, pneumonia, and bronchitis, the patient seems to be better when the croup kettle is kept going continually night and day. I have a case in mind where an infant of six months with capillary bronchitis required the continuous use of the croup kettle for seven days and nights. Whenever the steam was stopped, he seemed to tighten up and become worse. Of course, one must provide for the continuous flow of fresh air in a room when using a croup kettle without interruption.

FIG. 2.—Child held on the lap of the nurse; croup kettle in place.

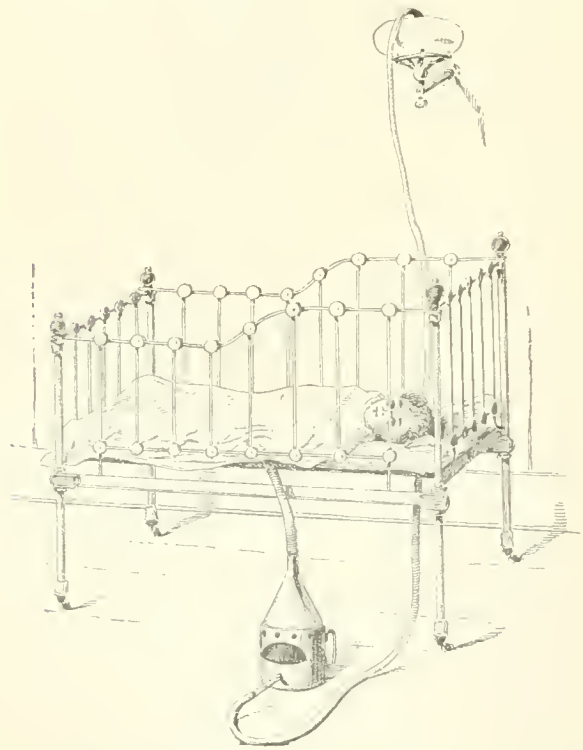

FIG. 3.—Child in a bath of hot dry air.

Tonsillitis.—When the tonsils are large and the throat is intensely red and swollen, much relief may be had from an occasional period of inhalation. The warm moist air has a marked beneficial action upon this swollen condition of the throat.

Having outlined briefly the diseases in which warm moist air is used as a therapeutic agent, let me name a few conditions in which the application of hot dry air, applied to the external surface of the entire body or part of the body is exceedingly efficacious.

Nephritis.—In treating an infant or child with nephritis, especially acute nephritis, where there is diminished urine, puffy eyelids, swollen ankles, and a dry skin, almost magical is the effect of a ten minutes' bath in hot dry air. These air baths may be given in the crib without disturbing the child in the least. The baby is placed upon a rubber sheet, which is covered by a white sheet. A covering of a sheet and one or two blankets is placed over the patient, excluding the head, and is tucked in well on the sides of the crib. (Fig. 3). Two safety pins are pinned to this cover and strings tied to these pins, so that the cover may be raised along the center to a height of ten to fifteen inches, thus making an air space between the cover and bed in which the child lies. This space is flooded with hot dry air generated by a kerosene lamp covered with a tin funnel with a long spout, or better, by the use of the apparatus described later on. After the patient has had this dry hot air bath, the skin should be rubbed dry. The head should be kept cool by the use of cold wet compresses.

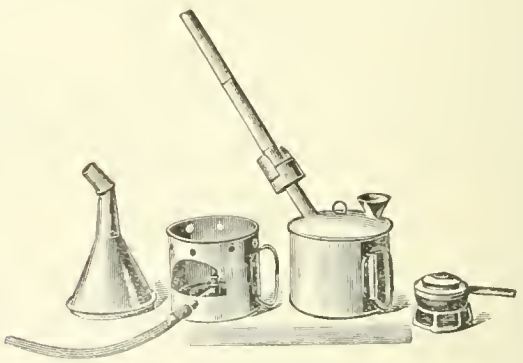

FIG. 4.—The complete apparatus.

Sprains.—Oftentimes one or two applications of hot dry air to a sprained joint are all that is necessary to effect a cure.

Rheumatism.—The use of hot dry air in cases of acute articular rheumatism is extremely efficacious. In older children with red, swollen, painful joints the application of the hot air bath to the joints two or three times daily will give great relief. The pain will disappear and the swelling will be reduced.

The application of hot dry air is recommended by some for the treatment of local septic infections and pneumonia, especially when accompanied by the pain of pleurisy.

Having given the various diseased conditions which are markedly relieved by the inhalation of warm moist air and by the application of hot dry air, let me explain in detail the methods of application by means of the improved combined croup kettle and hot air generator, which I have lately devised.

Having used various croup kettles during the past ten years, and having seen the evil effects of many of them, such as the danger of fire, scalds, etc., I came to the conclusion that an improved croup kettle was almost a necessity. The thought occurred to me to

combine the kettle with a funnel and asbestos spout for the application of hot dry air. The result is the following apparatus, which, although a trifle more expensive than the common croup kettles on the market, is far superior to them in many essential details.

It is almost impossible to upset it. It uses gas and can be kept going for weeks, if necessary, with no attention save the occasional addition of water. The fire pot may be turned upside down, and the burner will not drop out. The water boiler will not fall off the fire pot on the least provocation, nor will the cover and spout fall off when least expected. It may be carried from place to place while lighted with no fear of setting fire to the house, scalding the patient, or burning the hands. Many other advantages will suggest themselves when using this apparatus.

It consists (Fig. 4) of a tin funnel chimney, a fire pot containing a Bunsen burner for gas and an alcohol lamp; a water boiler with a cover; a jointed tin tube in two sections with a gauze chamber, and an asbestos tube. There should therefore be ten parts to the complete apparatus.

Fig. 5.—Apparatus for supplying warm vapor.

To Use the Croup Kettle.—If using gas, place the Bunsen burner in position on the bottom of the fire pot with the round flat base of the burner slipped under the two tin strips on bottom of fire pot. Have the long end of Bunsen burner protruding through the round hole in rim of fire pot near bottom. Attach one end of any ordinary gas tubing to a gas burner which is near the place where the croup kettle is to be used. Attach the other end of the gas tubing to the long end of the Bunsen burner (Fig. 5).

Fill the boiler half full of water and set it firmly on the top of the fire pot. Turn on gas at the key, and when the air is expelled from the gas tubing, apply a match to the Bunsen burner. Regulate flame at the burner by sliding the air shut-off one way or the other until the flame is blue and does not sputter or blow. If plain steam only is required, put on the cover to the boiler and connect the tin spout as shown in Fig. 5. If medicated steam is required, place a piece of surgeon's gauze or old handkerchief wet with the required medicine in the small gauze chamber; the steam will now pass through this medicated gauze and become impregnated. If there is any drip from the steam spout, it is caught by the lip of the gauze chamber and re-enters the kettle. The small tin gutter around the top of the boiler also prevents drip falling on the floor. The bottom being weighted prevents an accidental upset. By means of the two handles the kettle can be moved without fear of spilling or burning the hands. When more water is required, pour it through the small funnel in the boiler cover. If gas is not obtainable, substitute the alcohol lamp for the Bunsen gas burner.

The crib is draped with a sheet making a tent over the child, and the spout of the croup kettle is inserted under the edge of the sheet.

To use the apparatus for the application of hot dry air, insert the Bunsen gas burner (or alcohol lamp), as described above. Place the tin funnel chimney over the fire pot, and see that it fits tightly. Place the asbestos tube over the end of the funney chimney (Fig. 6).

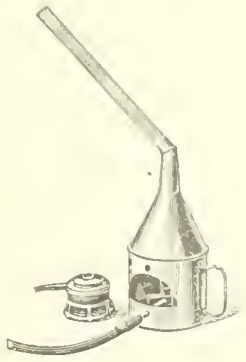

Fig. 6.—Apparatus for supplying hot, dry air.

Turn down the gas at the key, until the yellow flame is only about an inch high. (In the case of an alcohol lamp, use the small aperture in the lamp cover.) The hot dry air may be applied to the entire body, or to any part of the body, by covering the part to be treated with a heavy towel or sheet, always allowing some air space between skin and towel. This may be accomplished by two circles of stiff wire a few inches larger in diameter than the part which is to be treated, and placing these circles over the part; cover them with towel or sheet. Insert the end of the asbestos tube under this towel or sheet. Any degree of temperature may be obtained in this manner.

THE PSEUDO-UREMIA OF CHILDHOOD.

By WOODBRIDGE HALL BIRCHMORE, M.D.,

NEW YORK.

During the twenty years and three just past the writer has seen some dozen or more cases of illness in children and nine cases in young adults, in which the symptoms if examined superficially would certainly justify the diagnosis of uremia, which had been already made in at least a half dozen cases seen in consultation, yet to the writer it seemed certain that the comatose condition was due to a very different poison.

The cases seem to divide themselves into three groups by sex and age, but in all the pseudo-uremic coma was the important symptom in the opinion of those whose duty it was to care for these patients.

Group 1. Five cases in young women, three between thirteen and sixteen years, two aged seventeen and nineteen years respectively.

Group 2. Four cases in young men, two aged fifteen years, one aged seventeen years, and one aged nineteen years.

Group 3. Eleven cases. Six cases were in girls between three and twelve years, five cases in boys between five and thirteen years.

This group of twenty cases was sufficiently well defined and sufficiently well marked to justify a strongly held opinion as to the true nature of the illness and the causes of the typical groups of symptoms. It also appears that the typical and severe cases are very rare, and the writer wishes to insist that the diagnosis of uremia had been made by really skillful men in each of the cases, and in two of them there was special reason for the mis-

take because albumin was found in the urine, although the quantity was small.

Clinical Picture.—Eliminating all the personal symptoms, *i. e.* those which occurred in one case or two only, and considering only those which were present in all the cases, the group of symptoms representing the disorder appears as follows:

All the cases at the beginning complained of very severe headache; in the youngest children the parents or nurses "believed" that there had been "slight spasms" with causeless fits of crying or ill temper; in the older patients there was a history of a chill more or less severe. After the headache had lasted an hour or two the patients became sleepy, and before long were sunk in the strange lethargy which occasioned the alarm and caused the physicians to be sent for. When seen, the victims were sleeping soundly and it was practically impossible to rouse them sufficiently to gain anything in the way of coherent answer or useful information. The skin was dusky; in some cases it might have been called "bluish"; in others the term "of a purple hue" would best describe it. The *pulse* was slow and weak; in one case it had fallen below fifty; in another it was fifty-six to the minute; but the average was fifty-nine. The *respiration* was very faint, and anywhere from ten to fifteen to the minute. Cheyne-Stokes breathing is noted twice.

The *temperature* was very high; 102.4° F. and 103.2° F. were noted. In one case the temperature is recorded as 103.8° F., but is marked with (?), as if it was considered doubtful.

The *pupils* were spasmodically contracted in every case and were not sensitive to even very bright light. There was one exception to this contraction in which the pupil is said to have been dilated, the words used are "spasmodic mydriasis." This dilation occurred in the case of a young woman and the headache had been accompanied by disorder of vision previous to the comatose stage.

Whatever else might be the matter it was plainly to be seen that something had so neutralized the *besoin de respirer* that the patient would die if the condition was not at once neutralized. On that question no words were wasted by anyone, no matter how much opinions might differ in respect to causes, and the diagnosis of uremic poisoning made in the first three cases by the attendant physician was not considered at all in the discussion of the treatment. At the same time the absence of albumin seemed to exclude any such trouble; but had the albumin appeared in the first cases instead of in cases seen later, it is probable that a dangerous if not fatal mistake would have been made.

Taking the picture as it stood the cases had a most marvelous resemblance to muscarin poisoning, and since an analogue of muscarin can be produced by miscarriage of the digestive process there was something very suggestive in the condition.

In all cases the very first interference was to give a hypodermic injection of sulphate of atropine to stimulate the respiratory center, and it was given in sufficient amount to do this, and strophanthin by hypodermic injection instead of digitalis per os was used to steady the heart. Reaction began after some minutes in all cases. The breathing was noticeably better in all of them as soon as the atropine began to take effect, although the action was delayed probably by the extreme sluggishness of the circulation.

As soon as the patients could be roused enough to make it possible, a very large dose of an effervescing saline cathartic was given, and after a half hour this dose was repeated, no attention having been paid to the results if any from the first dose. In every single case the exhibition of the saline was very quickly followed first by the complete evacuation of the bowels, secondly by the equally complete disappearance of all the symptoms, although the length of time required for this latter varied; in one case the narcosis lasted in some small degree for ten hours after the emptying of the bowels; in another case the lethargy disappeared all but instantly, but the average time between the action of the saline and the disappearance of the symptoms may be put at three hours as a fair average.

While the cases just referred to are distinctly typical, they also probably represent the maximum severity, and there are possibly many much less severe forming a rather large group in which these cases should rightfully be included, a series of cases of indigestion or faulty digestion in which the poison which overpowers the respiration center is produced in a quantity quite sufficient to do very serious mischief, but also in quantity vastly less than in the cases here referred to. An additional interest is given to them by the strong resemblance of the symptoms to those of muscarin poisoning and the exceeding ease with which these various bodies neurin, cholin, and muscarin, exchange relations. The fact that the members of this group can be called into existence one from another by the simple process of oxidation and dehydration should never be lost sight of.

The record of sudden onset and the lack of any record of constipation also demands attention, indicating that in these severe cases the poison is either preformed or that the conditions needed for the rapid formation of large quantities exist.

In addition to this group a number of cases which may be described as chronic poisoning from the same cause are noted, in which the mother or nurse becomes accustomed to the somnolent condition of the child, who is allowed to grow worse and worse for a prolonged period, and finally dies suddenly, usually in sleep without medical attention. These cases cannot be treated in the summary fashion in which the acute cases can be handled because the patients are so weak that serious results would follow. In these cases the urine contains albumin, apparently in every case, and is also likely to contain indican. The mother will state that there is nothing the matter only the child "sleeps and sleeps," but the slow respiration and slow, weak pulse are diagnostic.

In these chronic cases the treatment seems to demand a very different method, at least so my memoranda appear to indicate. In these cases also the hypodermic syringe is an invaluable aid in treatment. because it is only by the use of this weapon that the physician can have any surety, almost any hope of obtaining reaction to the drugs administered.

Strychnine nitrate, strophanthin (digitalin doubtfully), and atropine appear to be the best weapons. In some cases very small doses of calomel, 1-8 grain every hour until effective, seem to be the most satisfactory. Some saline water to obtain effectual emptying of the bowels, of course, must be used, but the one thing to be feared is that the heart or respiration center will give out suddenly. The temperature, which is so high in the acute cases, is less markedly elevated. Probably the mother or nurse will say that the child has had a very high fever, but that this has passed away. The thermometer will probably indicate 99.3° F. to 100.5° F. seldom higher.

I have seen one case in which this condition had lasted for five days before professional aid was asked for. It was in a girl aged ten years, and it was more than a week before the pulse came out strong and full, showing how serious was the damage to the heart. One boy, aged twelve, in whom the poison had been acting for at least a week, rallied and seemed very much better, and then suddenly became comatose and died from heart failure. In these so-to-say chronic cases the albumin in the urine is the sufficient reason for the mistake in diagnosis.

Up to the present the information at hand gives absolutely no light on the reason for the formation of the poison.

If the writer's experience is any guide, this disorder of digestion is rare enough to be called uncommon and serious enough to be interesting. It would be very interesting if the condition could be traced to the habits in respect to food, because the group of poisons apparently concerned are all of them "substitution ammonias."

These cases also afford an excellent illustration of the range of usefulness which is gradually being predicated to hypodermic medication. How absolutely powerless we physicians would have been in the face of these cases if we had not this important weapon and preparations suitable for use therewith. More than one hundred drugs are suitable for use in this way, yet the manufacturing chemists do not seem to see the opportunity, for every alkaloid and glucoside can be used hypodermically if only suitable preparations are available, and the number of conditions in which they would be useful is simply legion. Ptomain-poisoning by other substances than the one causing these cases certainly occurs, and the physician who trusts to other methods than the hypodermic is surely taking long chances. Even when given *per os* the elegance and "civility" of the little pellets is very engaging, but they are absolutely essential in treating conditions like this to which I have applied the name of pseudo-uremia. The coma says the poisoning is uremic—but it is not so, and the ordinary methods of medication are simply useless.

A FEW MORE WORDS CONCERNING MICE AND PNEUMONIA.

By E. PALIER, M.D.,

NEW YORK.

Elsewhere* the writer has detailed a series of experiments which led him to the conclusion that house mice were the main factors in the causation of pneumonia. In this short communication the author wishes to consider briefly some well-known facts in connection with this disease, which will serve to corroborate the above conclusion, and which will at the same time find an easy explanation—facts which cannot be accounted for by adopting the old theories.

It would be unprofitable to repeat here at length what has been described elsewhere; but in order to make this paper more intelligible, we shall say that from experimental evidence the following statements have been made: Firstly, the microbe causing pneumonia is very polymorphous; secondly, a similar microbe was found in the mouths of all healthy individuals examined; and thirdly, the microbes which were found in healthy individuals or in those suffering from pneumonia were not virulent enough to cause such a disease when injected into animals like the rat, which are not very susceptible to them. On the other hand, these microbes acquired a great virulence when they passed through a susceptible animal, like the house mouse. Owing to the reasons stated above, the writer has thought that the most suitable name for the bacteria in question would be diplo-lanceco-bacilli-cocci, or for the sake of brevity, d. l. b. c., instead of pneumococci.

The previous theories were that the pneumococci, or, as the writer calls them, the d. l. b. c., might remain innocuous in the mouths of healthy individuals, but under certain circumstances they acquired virulence and caused pneumonia. How this virulence was suddenly acquired the authors who made such statements could not exactly tell. Netter thinks it depends on metereological changes, but he has not proven it by facts, it is simply a surmise. Microbes are affected by heat, chemicals, etc., but it yet remains to be proven that metereological changes, whatever Netter understands under such a term, affect the virulence of a microbe.

The question suggests itself, why is pneumonia more prevalent in winter than in summer? The d. l. b. c., or pneumococci grow at a temperature of from 20° to 42° C. The optimum of temperature is 35° to 38° C. The d. l. b. c. then should develop and thrive better in summer than in winter, if we accept the old theories, and pneumonia should be more frequent in summer, as are other infectious diseases, like cholera, for instance. The cholera bacillus is capable of growing at much lower temperatures than the d. l. b. c., and yet cholera does not easily develop in winter.

A great deal is being said about bodily depression as playing an important part in the etiology of pneumonia. But is the body more depressed in winter than in summer? Authorities practically agree that the disease in question is most prevalent in the months of December, January, February, and March. In March, especially, the disease is most prevalent. Is the body more depressed in these months than in July or in August for instance? Such statements are simply haphazard and should never have been entertained by any one who lays claim to scientific accuracy. Only scientific data should be accepted, but no indefinite, vague statements. We know, furthermore, that people apparently in good health may suddenly develop pneumonia, whereas people who are very weak may not get it.* The advocates of the depression theory will say that the former were depressed and the latter were not depressed enough. How far must one be depressed and how must the depression manifest itself?

Another theory recently advanced is that pneumonia is a mixed infection, and when the saliva of two or more persons is mixed its virulence is enhanced. The author of this theory does not say what microbes he found in the several sputa which he injected into animals, but simply states that when he injected into rabbits sputa of two or more persons, they proved to have a better effect than where the sputum of one person was injected. To make the experiment of any value it would be necessary to experiment with the cultures of the sputa and to know what one injects. When one injects sputum one does not know what he injects.

Medical News, November 18, 1905

*Healthy children are quite as liable to be attacked by pneumonia as those who are delicate, or cachectic, if not even more so." Keating's Cyclopedia of the Diseases of Children, vol. ii, p. 587

According to such a theory kissing ought to be fraught with danger, as the sputa are apt to mix and usually do mix together. In May and June, which are usually months for love-making and marriages, pneumonia ought to be most prevalent. Pneumonia ought also to be more prevalent in affectionate families where kissing is done to a great extent than in institutions like asylums where labial contact is not indulged in, and chances of the sputa mixing are very remote.

Authors on the whole agree that the pneumococcus is found in the mouth of almost every healthy individual. Now it is entirely absurd to imagine that every one carries within himself germs that at any time may become virulent enough to cause pneumonia. This savors more of mysticism than of science. If this were the case the human race would have by this time succumbed to pneumonia.

Nature, as a rule, supplies the healthy organism with means of defense against foreign intrusion. But, in the case of the d. l. b. c., nature has put into almost every healthy human being a dangerous enemy which at any moment may cause in him one of the most serious diseases, and also his death. Such a notion seems to me to be entirely absurd.

In my mind, as proven by my experiments, the d. l. b. c. which are found in the human being are far from enemies; on the contrary, they perform useful physiological functions in preventing the invasion of other microbes, and they act probably also as scavengers of the respiratory tract. In the stomach of the healthy human being there are usually found two microorganisms, yeast, and a small, slightly motile, rod-shaped bacillus which I have called *Bacillus chlorhydrici*, owing to the fact that it thrives in a medium containing a weak solution of hydrochloric acid.

Now these two microorganisms perform useful functions, a description of which will be given elsewhere.

What is meant to prove is that the bacteria which are our habitual hosts are not our dangerous foes, but on the contrary, our benefactors. This is in accord with the law of natural selection. For the d. l. b. c. to become virulent they must pass through a susceptible animal, and I find that the house mouse is most susceptible to them, and hence I have reached the conclusion that the house mouse is the main cause of it. I say the main cause and not the *only* cause, because there may be other susceptible animals which act in the same way; but never does a microbe acquire virulence from itself while remaining in the same medium, owing to meteorological changes.

Let us consider how mice cause pneumonia. In the months of December, January, February, and March, there are usually many mice in the houses, especially those whose plumbing is defective, and which are in a general poor sanitary condition. Mice, as is well known, work themselves through under sinks, and hence are mostly abundant in houses where the plumbing is not open, where there are many nooks and corners around the sinks. In trying to obtain mice for experiments I learned from many people that mice are more abundant in the house in the months referred to above than in the summer. Young mice seem to be especially abundant in the month of March. Now young mice are especially susceptible to the d. l. b. c. The young mice come into the rooms to look for food; they can easily get inoculated with human sputum. These mice, either through their feces, or after their death through their decomposing bodies, spread virulent d. l. b. c., which may cause disease in man either by inhalation or by inoculation through some abraded surface.

Now it is not easy to find dead mice for dissecting to see whether any of them actually have died from d. l. b. c.; but the author was fortunate enough in finding two young dead mice, which showed many d. l. b. c. in smear preparations made from the blood. Mice, as is well known, usually die in nooks and corners, and it is indeed very hard to find them after they die. But the fact that even one dead mouse showed in its blood the d. l. b. c. and the characteristic pathological changes in its various organs, goes a great deal to prove what has been said before.

In poorly ventilated rooms the virulent d. l. b. c., emanating from the feces of infected mice or from their decomposing bodies, become abundant and the chances of contracting pneumonia are great.

The above theory will also afford a plausible explanation for the duration of pneumonia. Virulent d. l. b. c. do not retain their virulence indefinitely, but lose it after the third or fourth subculture. When the exogenous virulent bacteria in question enter the human system, which is very resistant in regard to them, it takes from seven to nine days for the body to dispose of them; or in other words it takes them so long to lose their virulence in the new medium, the human body. One may infect himself with microbes whose virulence is well nigh exhausted, and then a much shorter time is required for the patient to get well. On the other hand, one may inhale a great quantity of very virulent germs and the body may then be unable to cope with them, and the case results fatally. It is impossible to explain the above phenomena satisfactorily by adopting the statement that the endogenous pneumococci, owing to metereological causes, or otherwise, suddenly become virulent.

321 East Thirteenth Street.

SOME OBSTETRICAL METHODS PRACTISED IN THE PHILIPPINES.

By Wm. DUFFIELD BELL, M.D.,

late major and surgeon, United States volunteers.

The popular belief that the child-bearing women of a barbarous and semicivilized peoples escape many of the pangs their civilized sisters undergo, would receive quite a setback were a careful investigation made. For a period of more than fourteen months, I was a resident of an inland town in the province of Rizal, on the island of Luzon, Philippine Islands, and during that time had leisure to devote to the careful study of obstetrical methods in vogue there. As a result of my observations there I was able to convince myself that the so-called ease and safety with which the semibarbarous peoples of the Philippine Islands were supposed to pass through the period of labor could be replaced in reality by tortures and the process could be followed by serious and far-reaching consequences. From the start the crude, interesting methods resorted to during the confinement of a native woman furnished food for considerable reflection. No attention was paid to any sanitary conditions of the patient or of the surroundings.

The patient, clad in the scanty garments worn by native women in the Philippine Islands, was placed upon a mat on the floor of the main room of the hut. The entire family, children, dogs, and those neighbors who could spare the time, ranged them-

selves, male and female, around the room in order to be present on this auspicious occasion. One slight tribute to the modesty of the woman in question was observed in the fact that her limbs were draped in her somewhat scanty garments. As soon as the first real pains manifested themselves and locomotion was somewhat impeded, the patient assumed the recumbent position, and a large, broad piece of cotton or linen cloth was passed around the abdomen and the ends passed under the lumbar region and hips. These ends being seized by four persons, two at each end of the cloth, and the persons being seated on the ground, with their bare feet pressed firmly against the body of the patient and made strong traction on the cloth so as to tighten it over the abdomen, increasing the pressure as required to assist the pains of expulsion. The bag of waters if not already ruptured, very soon broke under this method of procedure and as soon as any portion of the child presented it was immediately seized by a fifth assistant and traction made, in a more or less vigorous manner, in order to draw it forth regardless of consequences. Should any delay, natural under the circumstances, be occasioned, further aid was given in a more forcible manner by placing a plank about six or eight feet long by a foot wide and of suitable thickness transversely across the abdomen of the patient and upon this plank a native, man or woman, mounted barefoot. Slowly, but with considerable force, this assistant then raised himself on his toes and allowed the heels to descend forcibly on the board. The process was repeated for a considerable time, the first four assistants meanwhile tugging manfully at the cloth around the lower portion of the body. This last auxiliary process, viz., the plank with its superimposed weight, was usually effectual except in breech presentations, in which case a crude attempt was made at version, the hands of the assistant performing this important service being seldom in a proper sanitary condition to recommend them for such work. Few cases in which these various methods were used were free from laceration of either cervix or perineum, or both; and in some cases noted there was sufficient violence employed to cause rupture of the uterus and fatal results.

The birth of the child was followed by the expulsion of the placenta by the above means, and, should the process be delayed, forcible traction on the umbilical cord was made to such an extent as to tear away portions of the placenta, and often large sections of this body were left to find their way from the uterine cavity of their own accord. Weeks and even months later the results of such practice were noticed in the septic conditions which would naturally follow retention of the membranes. After the birth of the child the umbilical cord was severed by a blow from the bolo, a knife like a machete, carried by nearly every native man in the interior of the islands, and the end nearest the child was knotted. This was further reduced in length after the mother had bathed both the child and herself in a nearby stream, or well, which ablution was usually performed within an hour after the birth, and the newly-made mother then proceeded to take up her usual avocations, temporarily postponed by the above interesting event.

Notwithstanding these crude and somewhat violent methods employed to hasten the birth of a child, some few women and their offspring managed to escape without serious injury, and some even went through their confinement without the resort to artificial means. As there were no records extant from which any data concerning these cases could be obtained, careful notes were taken in one hundred and five cases to which it was possible to obtain access, and the results showed somewhat startling facts. Three were cases of twins. In two of these the mothers were uninjured and the children were safely delivered. In the third case, the woman was the daughter of the presidente or head man of the town; after one child had been delivered dead and with a broken arm, the presidente mercifully interfered and put a stop to the brutal methods employed and sought the aid of the medical officer on duty with the American forces in the town; through the efforts of this man the second child was safely delivered.

Almost superhuman efforts were necessary to secure proper sanitary surroundings and to enforce antiseptic methods, in consequence of the modesty which native women seem to regard as necessary in their dealings with persons of another race. This added to the many difficulties a medical man meets when called to attend native women. It is seldom that a medical man is called upon in obstetrical cases until native methods have been used and the patient's condition has become so grave as to force even a Filipino to recognize the inutility of any further torture. Extensive laceration of both perineum and cervix was noted in thirty-eight cases where it was possible to secure the proper examination, and six of these were further complicated by prolapsus uteri. Prolapsus uteri and inversion were noted in two cases which resulted fatally from hemorrhage, and septicemia. In four cases toleration of the condition of inversion appeared to exist, and the uterus became reconciled to its new conditions, its position, and surroundings, and the patients on an examination about twelve months later had apparently recovered perfect health. Inversion in these four cases was the result of traction from below, exerted in removing the placenta by forcible traction on the umbilical cord, and of the abdominal pressure from the plank with its superimposed weight. Metritis and endometritis existed in all of the thirty-eight cases examined. Five of these were traced directly to a gonorrhea, and two to venereal excess in newly married women, and which the rougher handling during the process of parturition aggravated. One case was of syphilitic origin. It may not be out of place to state that the venereal diseases met with in such great numbers in Manila and other seaport towns of the Philippine Islands are comparatively rare in inland towns where communication with the outside world is difficult and infrequent. Much venereal trouble has followed in the wake of the Spanish, Filipino, and American armies which have traversed the islands, while isolated towns and villages have escaped.

One case of an imperforate hymen was noted in a girl fifteen years of age, a native of a small mountain village about twelve miles from the town of Morong, Rizal Province, in which town I was stationed. The history of this case was as follows: the patient had never menstruated, though the native women frequently began as early as ten years of age; for more than two years every other month there had been intense pain over the left ovary and the uterus, lasting about four or five days; no flow was noted at any time, and during such paroxysms intense pain also existed over the bladder, accompanied by frequent micturition. This condition would cease for a period of nearly two months and then increase again, the interval between the paroxysms being only marked by tenderness on pressure over the uterus and left ovary, and also by a noticeable increase in the size of the lower part of the abdomen. The girl was an unusually well developed and muscular one for her age and race, and was engaged in

the usual agricultural pursuits of her family, which necessitated the carrying of heavy burdens on the head for long distances and hard manual labor. The attack, for which the attention of the medical man was required, was of greater violence than usual and overcame the prejudices of her family regarding medical attendance. She was brought on a litter from her home to the town and the medical man called upon to render her assistance in what the family fully believed to be a case of labor and for which the crude, interesting but ineffectual methods, (ineffectual in this case) mentioned above as being the usual method of procedure, had been resorted to. Examination of the patient showed great enlargement of the lower part of the abdomen, a largely distended bladder, enlarged and tender uterus, and the presentation of what resembled a bag of waters. The patient emitted the characteristic cries of one in labor as the pains attacked her at brief intervals. Examination of the vagina, which was entirely filled with the protruding mass, showed it perfectly dry. The membrane covering the mass felt hard, tense, and resisting, and was only slightly moved by the pains. The muscles of the abdomen were bruised by the use of the plank and its weight and by the tight cloth that had been applied in the early stages by the native assistants. The catheter was passed and the urine drawn to the quantity of over sixteen ounces, and relief was almost instantaneous, but no difference was noted in the size of the mass projecting into the vagina. Within an hour, the pains having begun again with increased violence and the attack having lasted for more than five days prior to the patient being brought in to me for treatment. the urine was again drawn, the parts below were carefully prepared for operation, and an incision three inches in length was made in the membrane presenting. Immediately two quarts and four ounces of thick, offensive, dark menstrual blood was discharged through the orifice and the pains instantly subsided, leaving only a slight abdominal tenderness. The membrane, through which the incision was made, was found to be an imperforate hymen nearly three-fifths of an inch in thickness over its entire surface, both in the center and at its attachment on the sides. For twenty-four hours a hot vaginal douche of a saline solution was administered every three hours, and on the second day, following the one on which the operation was performed, the patient walked home. Repeated examinations made monthly showed no further trouble, and regular and painless menstruation followed.

In the remaining seventeen cases displacement of the uterus was noted in nearly every case, and in all there was found on later examinations a chronic endometritis with all the accompaniments of leucorrhea, metrorrhagia, menorrhagia, dysmenorrhea, tendency to abortion, which tendency was further aided in many cases by the use of certain herbs and even large needles in imitation of their so-called civilized white sisters. In a climate where all mucous membranes have a tendency to congestion it is not an unusual thing to find even the native woman menstruating two or three times in the course of a month, while the white woman, a resident of the islands for any protracted period, will find her menstrual flow greatly increased in quantity, and the frequency also may be such as to call for the relief of the bracing cold of a northern winter. Anemia, with its characteristic train of symptoms, is the leading symptom in the hemorrhagic type of endometritis, which there attacks native and white women alike.

The life of the native Filipino woman is comparatively short, due to her many pregnancies, much manual labor, insufficient food, and most of all to the crude, brutal, and ignorant practices which bring to her a suffering equally as great as that borne by her white sister.

THE CARE OF THE SICK OUTSIDE OF INSTITUTIONS.*

By BERTHA A. ROSENFELD, M.D.,

NEW YORK.

I HAVE been asked to write about the care of the sick outside of institutions. My paper speaks of the care of the insane, a very important part of the sick, for insanity is sickness. "Its victims are entitled to the same consideration as the bodily sick or injured," is a sentence I have read in an interesting medical report. I say its victims *are* bodily sick or injured. The mind is normal only while its physical basis is strong. If the mind be abnormal, we may presume there is also some physical abnormality, even though not always evident, for pathologists have not yet demonstrated with regard to all mental affections.

To cure the diseased mind, one cannot give too much attention to the body, whose strength, even when apparently sound, has some impairment when mental balance has been lost. Care can never be given efficiently or scientifically to all when large numbers are being dealt with under one administration, for the needs of the individual must constantly give way to the urgent needs of the many. So our State Institutions for the Insane, of which we are so justly proud, prove but a makeshift, because there is not money enough to care for the poor in any other way.

There will not be time to deal fully with the ideal presentation of this subject, so I will just touch upon it. I hope to see the day when there will exist many Homes for Invalids, where voluntary cases of mental disease will be received; also a widely distributed number of regularly licensed houses for those cases which require commitment. In each of these I want a comparatively small number. I expect to accomplish much good work by utilizing religious orders for the care of the insane. In the Catholic Church there are trained organizations of men and women who work for the love of God and their neighbor, and who send their members to all parts of the world. By starting the first model houses on a solid foundation with religious in charge, no charitable plan for the suffering will be too bold to attempt. This is a matter of history.

In the meanwhile, let us try to deplete the ever-growing supply of mental invalids to the big institutions. Let us prevent many acute cases from becoming chronic, by giving them real care from the first. It would be deemed inhuman were a typhoid fever or a pneumonia patient obliged to wait two or three days for a legal process before skilled treatment could be given; the same would be the opinion regarding a surgical case. Yet in mental disease there does occur this often fatal delay of necessary care. It is an evil resulting from the legal measures required to prevent any unjust commitment. This protection for the many works injury to some.

How can we remedy this cruelty to so many in great suffering? In Germany, every university town has its psycopathic hospital. All crowded city districts should have these special hospitals for the treatment of acute cases of insanity. Our New York State Commission of Lunacy has taken active measures to establish two in Greater New York. There should also be mental wards in the general hospitals.

Mental patients are entitled to the consideration of

*Read before Sixth New York State Conference of Charities and Correction.

a general hospital. To those in whom has developed delirium and consequent irresponsibility, a general hospital should be open just as surely as to a critical surgical or medical case. The longer a disease goes unchecked, the less power remains in a patient's own system to throw it off. In very many cases of mental illness fear is an element of the disease itself, and this makes the physician's work more difficult. One of the first steps in the curative process is to establish confidence in the patient's mind. Confidence helps to quiet the nervous system, which is a dominant influence in resisting disease. This quieting of the nervous system is accomplished more quickly in a familiar environment with a well-known physician in attendance. Where will these be found? In a hospital near the patient's own home.

The consideration of environment is of great importance in the treatment of mental disease, for a consciousness of surroundings is very often most keen among the insane. How many of you have ever seen a ward of excited insane patients? Do you remember your fear and horror? Had you been ill at the time, would you have escaped an injurious effect? Yet it is almost a daily occurrence for a sufferer with a sensitive and disordered imagination to be cast into the midst of sights which it often takes years to drive out of the memory of an absolutely healthy mind. If we fully realize the conditions, the only rest from the thought of them is in work to make widespread measures for their relief.

All authorities on insanity agree that more is accomplished by means of moral treatment or appeal to the mind than by any form of medication. The foundation of success in treatment of the insane is sympathetic relations, and these can only be brought about by careful study of the individual cases. Any one who has made this careful study of many cases must reach the conclusion that cheerful companionship will be a very forcible appeal to many a diseased mind. This is the tonic treatment administered by a friend of my own—a woman who has received the insane into her home for the past twenty years. She can accommodate about eight invalids, and usually has some sane boarders in the house as well. The location is a small town, where at first the neighbors looked on critically. Now they aid by supplying the required cheerful and varied companionship when told there is a patient who will profit by seeing them. One woman cured in this Home for Invalids is especially worthy of mention, as she was pronounced incurable in two institutions. The husband had little hope when he brought her to this third place, as she was over sixty. At the end of five months he was able to take her home, and now they both return occasionally to show the continued good health resulting from the benefit of individual care. In the institutions, forced feeding had been considered necessary, as refusal to eat was a somewhat discouraging feature of the disease. In the Home for Invalids it sometimes took two hours to persuade the sufferer to take a glass of milk, but patient persistence won the day, with the resultant cure. This would not have been likely in a big institution.

Where small numbers are cared for, the motor restlessness characteristic of active mental disturbance may be permitted to some extent, and this will be beneficial to the individual patient. To restrain a harmless physical activity will breed resistance in the patient, and may result in undue violence on the part of the attendants. This is not only an outrage upon the patient, but it is also in direct opposition to the process of cure.

The fear already in a patient's disordered mind is often intensified by the sights he witnesses when put in a large institution for the insane, no matter how kind may be its executive management. It is impossible to estimate the number of cures prevented by this aggravation of the diseased condition as a result of the very surroundings which are supposed to cure. If the needs of the individual be protected, many acute cases of so-called insanity may prove no more serious than a prolonged delirium, and much useless suffering will be prevented, not only for them, but also for those whose disease is chronic or incurable. A number of chronic cases may recover even after years of illness, but it is less likely if they are lost sight of amongst hundreds of others.

Some of the opinions suggested in this paper are fully confirmed by the three annual reports of Ward F in Albany Hospital. In this hospital, Ward F deals with mental cases, coming directly, or developing in the other wards. The reports have been written by the attending specialist, Dr. Montgomery Mosher, to whom is due this most intelligent step in the care of the insane. For what is care of the sick? Evidently that which hastens permanent cure. Dr. Mosher's reports show that the real care of the insane is given in the Albany Hospital District, the opportunity for such being near at hand. I fully agree with his published opinion that there can be no greater charity than that which promotes the recovery from acute attacks of mental disorder.

Within the fortnight I have been asked where to send a case of acute mental disease. It is that of a woman who cannot pay for care. The physician in attendance claims that injury would be done by sending her to one of the big institutions. It is urgent that the invalid be cared for suitably, or the result will be prolonged and perhaps permanent illness, for speedy treatment is of paramount importance in cases of acute insanity.

I cannot but deplore the fact that we have no State provision for these borderland cases, nor for those among the poor who have recovered so far that removal from institutional care would be of great benefit, and yet who are not quite ready for absolute discharge. This need is filled in Massachusetts by the boarding-out system in homes near the hospital and under supervision of the hospital physicians. This has likewise been the method employed to relieve the crowded asylums in Berlin since 1888. Scotland has also had splendid results from this boarding of the insane in families. In Belgium and France the colony plan has worked much good, and thus have been established in all these places those sympathetic relations between the insane and their caretakers which is the foundation of success in their cure.

The increasing numbers of the incurable insane is undoubtedly due to lack of care in the beginning. It also seems as if all research in mental disease at this time is centered in the laboratory. The microscopical analysis of the brain of a dead patient does less good, because the living in many hospitals may not even enjoy rest at night, because of the screams and cries of their afflicted fellow patients. I cannot forget the facial emaciation of a man whom I saw in a well-known private institution where I spent some days to observe methods employed. The resident physician himself told me that what I saw was caused by weeks of unrest due to a continued noisy spell of a nearby patient. The condition was all the more pitiable because the institution was receiving only patients who could pay, and the grounds were spacious enough to have all the scattered buildings required to give comfort to each class of patients.

This is essentially an age of prophylaxis. This principle should be applied to the care of the insane. Germany sets an example well for us to follow. Besides having a psycopathic hospital in every university town, there is in Munich a new psychiatrical

clinic which we have reason to believe fulfils to the greatest degree anywhere existent the essential conditions and requirements of a modern hospital for the insane. These requirements I give in the words of Dr. Stewart Paton of Johns Hopkins University, as expressed in his forthcoming treatise on the treatment of mental disease:

"1. Ease of access. The institution should be near to or within the limits of a city.

"2. A limited capacity, in order that every individual patient may be made the subject of special study.

"3. Perfect construction, equipment, and organization, in order that a thorough and energetic treatment can be undertaken for all patients for whom there is hope of recovery.

"4. A relatively large staff of physicians and nurses.

"5. Ample provision not only for the teaching of students, but also for the prosecution of post-graduate investigations and research in clinical psychiatry, psychopathology, and in anatomy and pathology of the nervous system.

"6. The ready admission of patients and their prompt transference, when necessary, to other more appropriate institutions, and provision for outdoor and voluntary patients."

I cannot close without congratulating the administration of our public hospitals for the insane, upon the fact that many of these institutions employ more than the one resident woman physician required by law. The private institutions, as a rule, overlook the fact that great suffering is often added to that already existing in the mind of an insane woman if a man physician be in attendance. This is one more plea for my subject, for were these women patients outside of institutions, those physicians whom the individuals needed would be employed, and the result would be the care of the sick.

257 East Seventy-first Street.

A Study of Mental Diseases Associated with Cerebral Arteriosclerosis.—Albert M. Barrett has analyzed clinically and anatomically a graup of sixteen of these cases. Of ten of these, concerning which information could be gained, seven had a hereditary history of insanity or shocks. These latter as a rule occurred in antecedents during their senile years. There wasm not one history of excessive alcoholism. The average age of fifteen cases was above sixty-eight years. The duration averaged three and one-half years. Eight out of fifteen cases gave a history of shock, and in all except one mental symptoms were noted before the shock. Six were aphasic. In five this was a simple paraphasic disturbance, while one had a total aphasia following hemorrhage. Out of twelve cases in which the condition of the superficial arteries was noted, signs of sclerosis were noted in eleven, six gave clinical evidence of heart lesion, and seven of nephritis. Knee-jerks were noted in twelve; eight times they were normal, twice unequal, and twice they were exaggerated. The pupils were normal in ten, sluggish in two; there were unequal reactions in one, in four they were of regular outline, and four were of unequal size. None of these cases were free from arteriosclerosis of the vessels of the internal organs. Twelve practically presented general arteriosclerosis. In thirteen the vessels of the circle of Willis or their branches were sclerotic. In eight cases this sclerosis was limited to the larger brain vessels, while in eight it involved the finer cortical vessels, or both. The average grain weight was diminished. Eight patients had some time during their disease an apoplectiform attack; five of these had cysts or areas of coarse lesion; in the other three there were very severe changes in the finer cortical arteries. There were cysts indicative of old brain lesions in four cases in which there was no history of shock or clinical evidence of focal lesion.—*American Journal of Insanity.*

Two Eye Diseases of Children of Interest to the General Practitioner.—H. C. Moffett refers in this paper especially to phlyctenular keratitis and phlyctenular conjunctivitis. These affections are the result of the same pathological process. Phlyctenular conjunctivitis begins as a small nodule in the conjunctiva, at or near the edge of the cornea. It is caused by an efflorescence of round cells which raise up the conjunctival epithelium and then break down to form small ulcers. There are generally two or more of these ulcers, and in certain cases the entire cornea is surrounded by them. A number of vascular triangles with apices at the efflorescence are formed by adjacent conjunctival vessels which run directly to the elevations. These triangles are very characteristic of the disease. When the nodules form on the cornea the disease is known as phlyctenular keratitis. The large number of these cases are seen among the poorer class of children. The subjective symptoms are contradictory and variable. There is usually much lacromation and photophobia. The prognosis in phlyctenular conjunctivitis is favorable. In phlyctenular keratitis the prognosis must be more guarded. Here there is a possibility of secondary infection. In the diagnosis of phlyctenular keratitis it must be decided whether or not there is a deep advancing infectious ulcer. A bright illumination will demonstrate the superficial character of the lesion. Treatment of these diseases is local and constitutional. Proper diet and hygienic measures must be enforced. The hypophosphites are valuable. In phlyctenular conjunctivitis, a two per cent. yellow oxide of mercury ointment should be rubbed into the lesions by manipulation of the upper lid. If there is a great deal of irritation, however, it is better to begin with an impalpable powder of calomel followed in a day or two by the yellow oxide. In phlyctenular keratitis the yellow oxide is valuable in the cases presenting vascularization. But when this is not present and there is great irritation, a one per cent. atropine solution is used for a few days and then followed by mercurial ointment. Smoked glasses are always a necessity. The writer in conclusion calls attention to the remarkable disparity between the pathological indications and subjective symptoms found in phlyctenular keratitis.—*Iowa Medical Journal.*

Death Following Scopolamine-Morphine Injection.—J. C. Sexton reports this case. The patient, 47 years old, had been in poor health for five years, especially on account of excessive bleeding from the uterus. A uterine fibroid was found to be present and operation was decided upon. In all respects the patient gave no evidence of disease of any organ aside from the uterus and ovary, although the effect of the severe hemorrhages on all the organs was apparent. The hemorrhage was distinctly menstrual. Aside from this trouble, the patient had never had a severe illness. On account of sleeplessness the patient was given ten grains of trional at 8:30 P. M. on the night before operation. Menstruation came on some time after midnight. At 7:30 A. M. she was given by hypodermic injection scopolamine hydrobromate 1-100 grain and morphine sulphate 1-6 grain. In fifteen minutes the patient was sound asleep. In thirty minutes she was completely unconscious, and slightly cyanosed; the pulse was 120 and throbbing, and the respiration 20, but very shallow. The abdominal muscles and the intercostals were so rigid that it was impossible to compress the lower chest and epigastrium. Although every effort was made to resuscitate the patient she died at 9:15 A. M. without the least response to stimulants, pain, heat, flagellations, or changing posture. The heart continued to beat for a while after the feeble respirations ceased. After death a fibroid uterus and left ovarian cystoma were found. Unusual pelvic engorgement was present. This report shows the effect even of a single small dose of scopolamine administered to a weak patient. It also shows the uncertainty of action of this drug. Although excellent results have attended its use great care should be exercised in the choice of a subject.—*Lancet-Clinic.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, January 27, 1906.

THE CODE OF ETHICS AGAIN.

THE Medical Society of the State of New York is, we understand, to be asked, at the Albany meeting next week, to vote upon the adoption of the code (now weakly called the "principles") of medical ethics—the exact wording of the resolution to be voted upon being: "The principles of medical ethics of the American Medical Association, being suggestive and advisory, shall be the guide of members in their relations to each other and to the public." Before this indefinite resolution, drawn up in faithful imitation of the wishy-washy style of the "principles of medical ethics" is put to a vote, it should be amended so as to mean one thing or the other. The members of this great Society, the parent of the American Medical Association, are to be asked to stultify themselves (we use the term in its legal sense) by resolving to adopt as a guide of conduct a set of turgidly phrased truisms which are expressly stated to have no binding force! If they are merely "suggestive and advisory," why waste time in voting on them? Either there should be a code of ethical laws binding upon the members of the Society, under pain of expulsion, or the medical practitioners of New York State should be left to worry along—as they have worried along very well for about a quarter of a century—with only the Golden Rule and the law of the land to guide them. The adoption of this uncertain resolution would leave them where they are to-day and would only convict them of a lamentable lack of humor that would be ludicrous were it not humiliating. More than twenty years ago the Members of the Medical Society of the State of New York came to a realizing sense of the fact that they were full-grown men and fairly honorable, and they cast aside the antiquated rules of conduct which were even then as dead as the blue laws of Connecticut. Now the self-constituted mentors of the American Medical Association ask them to recognize officially that the code of ethics is dead—being only "suggestive and advisory"—and nevertheless to adopt it as a guide "in their relations to each other and to the public"!

What is this code, or these principles, suggestively and advisorily to guide men still presumably in possession of their reason and their risibilities? "Physicians shall not only be ever ready to obey the calls of the sick and the injured, but shall be mindful of the high character of their mission and of the responsibilities they must incur in the discharge of momentous duties." "Every patient committed to the charge of a physician shall be treated with attention and humanity, and reasonable indulgence shall be granted to the caprices of the sick." "Ordinarily, the physician shall not be forward to make gloomy prognostications." "The physician shall be a minister of hope and comfort to the sick, since life may be lengthened or shortened not only by the acts but by the words or manner of the physician, whose solemn duty is to avoid all utterances and actions having a tendency to discourage and depress the patient." "The opportunity which a physician has of promoting and strengthening the good resolutions of patients suffering under the consequence of evil conduct ought never to be neglected." "Everyone on entering the profession, and thereby becoming entitled to full professional fellowship, incurs an obligation to uphold its dignity and honor, to exalt its standing, and to extend the bounds of its usefulness." "There is no profession from the members of which greater purity of character and a higher standard of moral excellence are required than the medical; and to attain such eminence is a duty every physician owes alike to the profession and to patients." "It is incumbent on physicians to be temperate in all things, for the practice of medicine requires the unremitting exercise of a clear and vigorous understanding, and in emergencies—for which no physician should be unprepared—a steady hand, an acute eye, and an unclouded mind are essential to the welfare and even to the life of a human being." "Physicians shall not, as a general rule, undertake the treatment of themselves nor of members of their family." "The broadest dictates of humanity shall be obeyed by physicians whenever and wherever their services are needed to meet the emergencies of disease or accident."

We have transcribed only a few of the gems of this unequaled collection of Tupperian platitudes, but there are more. Dr. Benedict, in the MEDICAL RECORD of December 9, 1905, and Dr. Sturgis, in the present issue, have exposed the inconsistencies and the hypocrisies of these principles, and the latter has also drawn special attention to their ludicrous phraseology. It is inconceivable that a body of practical men, hard-headed and endowed, we trust, with a saving sense of humor, will write themselves down — subscribers to these Sandford-and-Mertonish moral maxims. If the medical practitioners of New York State cannot be trusted to be decently honorable and charitable without rules of conduct to teach them the way, let us, petition the two gentlemen of Chicago who have solemnly signed this absurd document to give us, of their benignity, something virile and mandatory which we can accept, if we really must return to leading strings, without total loss of self-respect.

SEASICKNESS AS A CAUSE OF ACUTE PSYCHOSES.

MAL DE MER in its various aspects may well be regarded as a state of severe bodily and mental exhaustion, comparable in its effects with those disturbances which are brought about by protracted labors, by extensive hemorrhages, by severe prostrating diseases, etc., but it has rarely been associated with the production of a true phychosis. Con-

ditions of acute delirium are not at all uncommon in seasickness, but it is very doubtful whether these are as a rule true psychoses, and in most instances they can readily enough be traced to alcoholism or to inanition. But that acute insanity may arise, however, during an attack of seasickness is well shown in a case reported by M. Dobrschansky (*Centralblatt für Nervenheilkunde und Psychiatrie,* November 1, 1905). The patient was a woman with several children, who, although greatly debilitated and weakened both in body and mind, and subjected for a time to much worry and excitement, had undertaken to cross the ocean. During the trip, which was a very stormy one, she was seasick a great deal, and suddenly developed a typical acute hallucinatory insanity, which failed to subside when the voyage was completed. Several months elapsed, during which time she was under treatment in a hospital, before a restoration to the normal mental condition took place.

It is rather a difficult matter to explain the etiological connection between these two conditions; and whether the insanity was the consequence or merely an accompaniment of the seasickness, cannot be decided with the data in hand. The idea, largely prevalent, that the latter is probably due to an autointoxication dependent upon a retention of metabolic waste products in the body, brought about by a temporary functional insufficiency of the excretory organs, does not afford a sufficient explanation of the origin of the mental disturbances. One of the modern conceptions of amentia, however, ascribes this to a form of intoxication, which would suggest the possibility that there are certain underlying factors which constitute a common cause for both complaints.

It seems more reasonable, however, to approach the subject from a different standpoint. We often see strong and healthy individuals completely prostrated and depressed as the result of the exhaustion, the cerebral anemia, the repeated concussions to which the internal organs are subjected, and a number of other well-known symptoms which are attendant upon an attack of seasickness. A much more serious symptom-complex would necessarily be expected in a case in which a person is already debilitated and weakened by severe illness, worry, or excitement, when there is added to this the shock and depression resulting from an attack of seasickness. There is a good practical lesson to be drawn from the narrative of the case above mentioned. The conditions referred to would apparently constitute a reasonable contraindication against indiscriminate advice in every case with regard to the good effects to be obtained from a sea voyage. There are undoubtedly certain mental and physical states in which, instead of being a benefit, such a course of action would constitute a decided detriment, so that the depressing and exhausting influences of a possible attack of seasickness should always be borne in mind when an ocean voyage is prescribed as a therapeutic measure.

The "Philippine Journal of Science" is a new monthly journal which has been established under the auspices of the Bureau of Government Laboratories, Manila. The journal will treat of all branches of science, but especially of medicine.

THE QUESTION OF FOOD PRESERVATIVES.

Ice, sugar, salt, and hermetically sealed receptacles have long served as legitimate and practically harmless means for preserving articles of food and drink until desired for future consumption. To overcome the inconvenience or expense of their employment, other methods have gradually been adopted, among the most common of which is the addition of chemical substances possessing mild antiseptic properties. Not only preservatives, but a large variety of other materials of doubtful character are being added for the purpose of imparting extra color or flavor. The idea has been gaining ground that the introduction of these substances exerts a deleterious influence on the organism, especially if they are taken more or less continuously, and efforts have been made by various States to abolish or restrict their employment. This has now been supplemented by legislation enacted or about to be enacted by the National Government, preliminary to which Congress delegated the officials of the Department of Agriculture to institute an investigation of the subject. Among the first of the reports to appear was that on the use of boric acid and borax as preservatives and their effect on the system, which was based on observations made by Dr. H. W. Wiley and others. These were made on a number of volunteers who agreed to live for a certain period of time under prescribed rules and regulations and were given the drugs noted with their meals. The experiments were necessarily surrounded by difficulties and some of the results obtained were rather uncertain, yet Dr. Wiley felt convinced, as stated in his report, that the continued administration of the preservatives in question to these persons produced a slight diminution in body weight, interfered with nitrogenous metabolism, and caused an increased secretion of phosphoric acid. In addition, there were disturbances of the appetite, the digestion, and the general health.

The chemical rather than the medicinal aspects of the question form the basis of the research and some of the evidence is marked by contradiction, but there are many elements of truth, and criticism can be directed only to the insufficient number of cases studied and the short period during which the latter were observed, rather than to any defects in the methods employed.

It is quite natural that a great deal of opposition should be manifested by the commercial interests affected by the provisions of a pure food bill, which should come before Congress and in which the manufacture, importation, or sale of food articles containing deleterious preservatives, coloring matters, etc., was absolutely forbidden. A law of this kind would mean a restriction of business and profits to which those affected would not submit without a struggle, and the opposition has extended to many countries outside of the United States. The attack has not been limited to the commercial aspects of the case, but the investigations of the department, as published in Dr. Wiley's report, are questioned by no less an authority than Prof. O. Liebreich of Berlin, the noted pharmacologist, in a pamphlet recently printed in Berlin. Nominally this is an effort to deny Wiley's claims, but practically it will be considered by those most interested as a defense of a system of food preserva-

tion by boric acid and similar substances. The criticism to which the Berlin professor subjects the report is marked by a spirit of ridicule and animosity, and to party politics is assigned the motive for the entire investigation. The disturbances to the general health which were noted are calmly attributed by Liebreich to faulty hygienic surroundings, to improper administration of the preservatives, and in some of the cases to idiosyncrasy. Granted that some of Dr. Wiley's conclusions have been hastily drawn and are based on insufficient evidence, most of us will agree with the main contention that the use of such preservatives must in the end be harmful to the organism, and even if this cannot be proved by laboratory tests, there remains a certain amount of clinical evidence which is more difficult to contradict. It is to be hoped that the publications of articles such as that alluded to will not stay the progress of the movement and that the production and sale of food supplies will be surrounded by restrictions sufficiently rigid to guarantee to the purchaser their purity and freedom from possible harmful results. Certainly if anything is added to any food preparation, whether it be coloring matter or preservative, the purchaser should know it, and then it would rest with him to buy it or leave it alone.

THE ENDONEURAL INJECTION OF TETANUS ANTITOXIN.

The prognosis attending the employment of antitoxic serum in tetanus seems to depend on two conditions—the time at which the serum has been administered and the mode of its application. The prediction made by von Behring that a reduction in the mortality of from 15 to 20 per cent. would result from injections of antitoxin, if this were done immediately on the first appearance of tetanic symptoms, has, unfortunately, not been fulfilled, and, in fact, it is in precisely these early cases that poor results have been obtained. The antitetanic serum has been employed in a variety of ways, by subcutaneous, intravenous, subdural, and intracerebral injection, without any agreement having been reached as to which of these was the preferable one. In addition to the foregoing, Meyer and Ransom, in 1903, suggested that the injections be made directly into the substance of the nerves, but this proposal met with little response, and we find reports of only a comparatively small number of cases in which this method was adopted. The majority of these were observed by John Rogers (Medical Record, July 2, 1904, and *Journal of the American Medical Association,* July 1, 1905), who reports five recoveries in a series of eight cases in which endoneural were used in combination with subdural and intravenous injections. Two of the patients who succumbed to the disease presented very extensive injuries of the soft parts, and offered a most unfavorable prognosis for any form of treatment. The percentage of recoveries must therefore be looked upon as very favorable.

Another successful case, treated in the same manner, has more lately been reported by P. Clairmont (*Wiener medizinische Wochenschrift,* December 7, 1905). In this patient, a little boy, tetanus developed from a severe compound fracture of the forearm. The conditions were rendered particularly bad by the presence of a malignant edema and an additional infection by a bacillus of the colon group. The period of incubation of the tetanus was six days, and the only way in which it was believed the original focus could be eradicated was by amputation of the arm. Some 200 units of tetanus antitoxin were injected subcutaneously with the idea of combating whatever toxin was still uncombined in the blood, and 100 units were introduced directly into the amputation stump without any difficulty at the time of operation. The effects of the antitoxin were developed slowly, but the boy finally made an excellent recovery. This good result in a very unfavorable case can fairly be attributed, it seems, to a combination of the local and the systemic treatment, and taken in connection with the observations made by Rogers, furnishes a sufficient plea for a further trial of the method, which does not appear to be attended by any special danger or difficulty in execution. When an amputation is rendered necessary the conditions are simplified, as no further exposure of nerves is required. The distribution of the tetanus toxin through the system makes it obligatory to combat its effects in all their manifestations by every means at hand, and the suggestions here referred to simply open up, as it were, an additional avenue for treatment.

The Treatment of Soft Chancre.

The application of heat locally to chancroidal ulcerations is the essential point in a method advocated by E. Welander (*Wiener klinischtherapeutische Wochenschrift,* November 19, 1905). It has already been claimed by others that a temperature of 40° C. will destroy the virus of this contagion, and Welander observed in addition that in individuals who may be afflicted with chancroids, the onset of any acute febrile disease with a constant temperature of 39° to 40° C., lasting for several days, apparently brought about a rapid improvement in these lesions. This seemed to be independent of the nature of the illness, and is attributed by the writer solely to the high temperature. He also subjected this observation to experimental test by attempts at inoculating with the secretion from chancroids, patients who happened to be afflicted at the time with an angina or other acute febrile disturbance. The results were always negative, whereas the control experiments in individuals with normal temperature were invariably positive. Welander therefore proposes the application to the ulcer of heat obtained from water circulating in a coil of small leaden pipes, and describes a special form of apparatus for this purpose. He has employed this method for a number of years, with uniformly good results. In from one to two days the ulcers are clean and granulating, and then irrigations with hot boric acid solution and the application of dusting powders bring about a rapid healing of the raw surfaces. The only disadvantage in the method must be referred to the complicated apparatus necessary, which can be employed only in hospitals or specially furnished apartments. A modified, but much less effective substitute is also proposed. The patient is directed to immerse the affected area in hot water of a temperature of 50° C. for periods of from 15 to 20 minutes, several times daily. The writer also used the method with good result in other forms of ulceration and likewise in trichophytosis.

The Value of a Therapeutic Card-Index in Practice.

Many physicians whose time for reading and study is very limited have found a therapeutic card-index to be the most useful aid imaginable to their daily work. All that is needed for such an index are some blank catalogue cards, such as are sold by the stationers, and a box or drawer to file them in. A few blank cards are kept on the desk, and when the physician comes across a useful therapeutic hint, a practical prescription, or a surgical suggestion which can be used in his work, he simply writes the information on the card and files the latter under the heading of the disease or condition with which it deals. The keeping of such an index engenders the habit of looking for what is useful and practical in the mass of reading that comes to one from various sources. Any given number of the Medical Record alone furnishes material for a large number of such cards, and each reader can cull what is most useful in his own work and what appeals to him as the most practical and best adapted for his purpose. Instant reference to the cards and great satisfaction in finding what he wants at once is the reward for the time thus spent, and as time goes on, the index gains in value as a ready reference guide in perplexing therapeutic emergencies.

News of the Week.

The Gibbs Memorial Prize of the New York Academy of Medicine.—Regarding this prize, the trustees of the New York Academy of Medicine publish the following correction of their previous announcement: (1) The prize amounts to two thousand dollars, this time; (2) The prize essays may be handed in October 1 (not January 1) 1907, or before that date. (3) The prize committee does not expect the "etiology, pathology, and treatment" of the diseases of the kidneys to be discussed with equal completeness, but will be satisfied with the thorough scientific consideration of part of the problem, provided an essay offered in competition contains new facts or discoveries or points of view of sufficient merit.

The Indiana Board of Medical Registration and Examination has elected the following officers for the coming year: *President*, Dr. J. C. Webster of Lafayette; *Vice-President*, Dr. M. S. Canfield of Frankfort; *Secretary*, Dr. W. F. Colt of Crawfordsville; *Treasurer*, Dr. Jas. M. Dinnen of Ft. Wayne.

Michigan Medical Registration Board.—In his annual report for 1905 Dr. Beverly D. Harison, secretary of the State Board of Medical Registration, announces that the office of the board will be removed from Sault Ste. Marie to Detroit. The change will be in the interest of economy for all concerned, as two-thirds of the applicants who appear before the board are in attendance at Detroit medical colleges or the University of Michigan. During the year the board issued certificates of registration to 240 persons, 120 being graduates of Michigan colleges, seventy-four being registered on examination, and forty-six receiving reciprocal certificates. The number of certificates issued in 1903 was 422 and in 1904 278.

Appointments at Bellevue Hospital.—The Board of Trustees of Bellevue and Allied Hospitals have accepted the resignation of Dr. Willam F. Fluhrer, who has been one of the visiting surgeons since 1882, and of Dr. Charles Phelps, who has been a visiting surgeon since 1878, and each of them has been appointed a consulting surgeon to Bellevue Hospital. Dr. L. W. Hotchkiss, who has been assistant visting surgeon for twelve years, and Dr. Thomas A. Smith, who has been assistant visiting surgeon for six years, have been promoted to visiting surgeons. Dr. James C. Ayer has been promoted assistant visiting surgeon in place of Dr. Hotchkiss, promoted, and Dr. Arthur S. Vosburgh has been appointed adjunct assistant visiting surgeon in place of Dr. Ayer.

More Model Tenements.—Another of the series of model tenements planned by several practical philanthropists of this city has been opened in East Seventy-eighth street, between Avenues A and B. The building embodies numerous improvements over the others built so far, yet the rents are only from $2.20 to $4.60 a week for two, three, or four rooms. There are no dark rooms, the building is heated by steam throughout, and gas stoves are provided for cooking

Pure Food Petitions.—Two petitions, signed by many of the best-known physicians of New York and Boston, have been forwarded to Washington in behalf of the passage of the pending bill prohibiting the adulteration of foods and drugs. The petitions urge the senators and representatives of the respective States to use their influence in aiding the passage of the bill and indicate its importance as a public health measure.

Mt. Sinai Hospital.—Gifts amounting to $135,000 were announced at the annual meeting of the Board of Directors of Mt. Sinai Hospital, held on January 14. In spite of the very extensive facilities offered by the new building it was stated that the hospital was pressed for room, and the erection of several additional wards was discussed. The figures made public showed that the general expenses of the hospital had been $296,000 and that the per capita cost had been reduced, despite the increase in the number of patients, from $2.51 to $2.18. Last year's report showed an average of 230 patients a day in the hospital, while there were at present said to be 404 in the hospital and 460 in the out-patient department. Of the total number of patients received during the year, 76 per cent. were gratuitously treated.

Ambulance Accident.—An ambulance from the Lincoln Hospital in which an eighty-year-old insane patient was being taken to the Harlem Hospital collided with an express wagon on the Willis avenue bridge on January 17. The collision threw Dr. Becker, the ambulance surgeon, and a policeman, both of whom were on the rear, to the flooring of the bridge, but they were not seriously injured. The ambulance horse became frightened and ran away, but was stopped before any further damage was done.

Epileptic Colony for Virginia.—The members of the general board of directors of the Virginia State Hospitals, at a meeting held at the Central State Hospital near Petersburg on January 11, adopted a resolution urging the Legislature to make provision for the establishment of a hospital for epileptics. The board appointed a committee to present the matter to the legislature and to prepare a bill for the establishment and organization of the proposed colony. At the same meeting Dr. W. F. Drewry, superintendent of the Central State Hospital was unanimously elected superintendent of the Western State Hospital at Staunton to succeed the late Dr. Blackford.

Sleeping Sickness.—An expedition to investigate this subject is to be sent to Africa by the German Government, which will appropriate 120,000 marks for the purpose. The leaders of the expedition are to be an investigator who is already well acquainted with protozoan parasites and their means

of transmission, a physician who has had experience on the East African coast, and a bacteriologist trained in matters relating to epidemiology. As no region under German control would furnish suitable opportunities for observation, it is proposed to send the expedition to the British possession of Uganda. The investigation would presumably require a stay of eighteen months. It is not yet known whether or not Dr. Robert Koch, who a short time ago returned from a journey along the African coast, will head the expedition.

The Yellow Fever Epidemic in New Orleans.—Reports compiled from official sources show that during the yellow fever epidemic of 1905 in New Orleans there were 10,804 known cases, of which 1,151 proved fatal. The average death rate, therefore, as shown by the records, was 10.46 per cent.

Death from a Synthetic Hypnotic.—That the dangers ascribed to the use of the modern synthetic remedies are not exagerated is shown by a recent death reported in the public press. The victim was a young school teacher who for insomnia took several tablets of one of the newer remedies usually affirmed to be particularly safe. It is not stated how many of these he consumed, but three hours after taking the first he was found in a stupor from which he could not be roused, and which ended fatally. The brother of the victim makes the remarkable statement, in a letter to the *New York Times*, that the physician who prescribed the drug had never heard of it, and ordered it at the request of the patient, knowing nothing of its therapeutic action, nor even the proper dose.

A Tuberculosis Exhibition is to be held in Springfield, Mass., during February under the auspices of the local anti-tuberculosis association. Preparations are also being made for a similar exhibition in Lowell.

Center District (N. H.) Medical Society.—At the eighty-fourth annual meeting of this society, held in Concord on January 9, the following officers were elected. *President*, Dr. T. M. Togus, Hooksett; *Vice-President*, Dr. G. P. Conn, Concord; *Secretary and Treasurer*, Dr. L. A. Sanders, Concord.

Eighth Councillor District (Ohio) Medical Society.—At the annual meeting of this society, held in Marietta on January 9, the following were elected as officers for the ensuing year: *President*, Dr. S. A. Cunningham of Marietta; *Secretary* and *Treasurer*, Dr. C. H. Higgans of Zanesville.

The New Bellevue Hospital.—After many weeks Judge Truax has dissolved the injunction of an unsuccessful competitor for the contract to build pavilions A and B of the new Bellevue. In a few days the two brick buildings on the southeastern part of the grounds will be demolished, and work on the new building will commence.

Annual Report of St. Anthony's Hospital.—The annual report of this Chicago hospital shows that 1,238 patients were treated in 1905, while 2,280 night watches were recorded

The Children's Memorial Hospital of Chicago will receive $25,000, realized from the Cribside Kirmess recently held.

The Children's Hospital Society of Chicago.—Dr. Frank Billings was reelected president of this society, at the annual meeting held recently, and Dr. Frank S. Churchill, secretary. In his address Dr. Billings announced that since the organization of the society, beds in children's wards in various hospitals in Chicago had increased from 290 to 450. It was proposed to establish tent sanatoria in all the small parks for the children of working mothers, where especially prepared milk might be obtained. Steps have been taken by the society to arouse public interest in the proposed Children's Hospital for Infectious Diseases.

Physicians as Dispensers of Liquor.—According to the Washington (D. C.) *Post*, Commissioner of Internal Revenue Yerkes has stated that druggists may use alcoholic liquors in compounding physicians' prescriptions and in making tinctures for sale in good faith for medicinal use only, without subjecting themselves to special tax as liquor dealers, but he decides that a physician cannot prescribe whiskey for a patient when not compounded with medicine, without involving himself in special tax liability, even though he prescribes it for use as medicine only.

New York Surgical Society.—At the annual meeting of this society, held November 8, 1905, the following officers were elected: *President*, Dr. George Woolsey; *Vice-President*, Dr. Joseph A. Blake; *Secretary* and *Treasurer*, Dr. John A. Hartwell.

Bequests to Philadelphia Hospitals.—By the will of Miss Marie Elizabeth Brasier the sum of $5,000 is bequeathed to St. Joseph's Hospital of Philadelphia for a free bed in the men's ward in memory of Charles A. Brasier. An additional sum of $5,000 is bequeathed to St. Joseph's Hospital for a free bed in the women's ward in memory of Mrs. Elizabeth P. Brasier. The sum of $10,000 is bequeathed to St. Vincent's Home and Maternity Hospital. A lot of ground containing four dwellings is also left to St. Joseph's Hospital.

Physician Obtains Verdict.—At a recent suit in a Salt Lake City court a physician who sought to recover $500 for his services as expert neurologist and oculist in a case against the Utah and Eastern Copper Company, was awarded $200 by the jury, although the defendants contested that $50 would be a proper fee.

Medical College for Lexington, Ky.—President James K. Patterson, of the Kentucky State College has asked the general council of Lexington, for an appropriation of $12,000 to establish a medical colege in connection with the institution.

United States Leprosy Station.—Dr. W. R, Brinckerhoff of Boston has been appointed pathologist to the Government Hospital, to be established on the Island of Molokai, of the Hawaiial. group.

New Secretary of the Ohio State Medical Board.—Dr. David N. Kinsman, the new Secretary of the Ohio State Board of Medical Registration and Examination, assumed charge of the office January 1. *vice* Dr. Frank Winders, resigned.

The State Board of Medical Examiners of California recently revoked the licenses of three practitioners, all of whom had been convicted in the U. S. district court of sending matter through the mails regarding criminal malpractice.

Los Angeles is planning to obtain its future water supply from the Kern river, nearly two hundred miles away, at a cost of more than thirty-six millions of dollars.

The "Journal of Medicine and Science," published at Portland, Me., under the editorship of Dr. Frank W. Searle, appeared for the last time in December, 1905. It was founded in 1891 by Dr. E. E. Holt.

For Cleaner Street Cars.—The dirty condition of the street cars of the Brook'yn Rapid Transit Company has given rise to many complaints, and the Borough President will appoint a committee of one hundred for the purpose of compelling the company to keep the cars clean and warm and also to improve the service in other ways.

Yellow Fever at Havana.—In spite of the asseverations to the contrary made by the authorities it is evident that yellow fever is not yet extinct at Havana. Two deaths from the disease have occurred recently, and several suspicious cases are said to be under observation.

A Race Suicide Investigation.—A member of the Massachusetts legislature has presented a resolution providing for the appointment of a committee to consider the matter of race suicide. The resolution states that the object of the commission shall be to consider what steps can be taken to counteract the tendency known as race suicide, and especially to prevent discrimination by landlords against tenants with children. The commission is also to determine what, if any, legislation in the premises is expedient or possible, and what means, if any, might properly be taken to arouse public opinion in respect to these evils.

The Health Department's New Transfer Boat, built at a cost of $75,000, was launched at the ship yards in Port Richmond, S. I., on January 18, in the presence of Health Commissioner Darlington and other city officials. The *Riverside* will transfer patients suffering with contagious diseases from all parts of the city to North Brother Island. She is 130 feet over all, and has twin screws. The lower deck is to be used as a hospital and will have eight separate rooms for patients, allowing contagious diseases to be completely isolated. On the upper deck are quarters for the crew and cabins for visitors to patients on the island.

Austrian Physicians Strike.—The physicians of the rural districts in Austria, in disgust at the niggardly scale of fees paid by the government for official services, have declared that unless the whole schedule of payment for public medical attendance is increased they will cease to serve in this capacity. It is stated that they receive only four cents a person for vaccinating the poor, whereas veterinary surgeons receive sixteen cents for inoculating each head of cattle, and qualified doctors for examining tramps and vagrants are paid less than barbers who cut the hair of the same individuals.

Michigan State Medical Society.—At a meeting of the council of this society, held in Detroit on January 12, 1906, Dr. A. P. Biddle resigned and Dr. B. R. Schenck was elected State Secretary and editor of the journal.

Obituary Notes.—Dr. Swan M. Burnett of Washington, D. C., died suddenly of heart disease on January 18. Dr. Burnett was born at Newmarket, Tenn., on March 16, 1847. He began the study of medicine under his father's tutelage and in 1866 entered the Miami Medical College of Cincinnati. In January, 1869, he was given charge of a military hospital at Nashville, Tenn. In the autumn of the same year he entered the Bellevue Hospital Medical College of New York and was graduated with the class of 1870. In 1873 he married Frances E. Hodgson, the authoress. After spending some time in Europe in special study he settled in Washington in 1876 and began to devote himself exclusively to ophthalmology, founding the Eye and Ear Clinic at the Central Dispensary in 1878. He established a post-graduate school of ophthalmology in 1881 and had made many important contributions to the literature of his specialty.

Dr. W. A. Payne of San Antonio died suddenly on January 10 of heart failure. He was soon to have gone to the Canal Zone in an official capacity.

Dr. F. P. Perry of Bucksport, Me., died on January 14 at the age of fifty-five years. He was graduated from Bowdoin College in the class of 1871 and received his medical diploma from the Long Island Hospital Medical College in 1873.

Dr. A. H. Cook of Chicago died on Monday, January 8. Dr. Cook was born in Mount Pleasant, Canada, in 1824, and was one of the oldest physicians of Chicago. He was on the staff of the St. Joseph's Hospital for a number of years and assisted in combating several epidemics which occurred in Chicago in the early period of its history. His son, Dr. John M. Cook, succeeded to his father's practice on the latter's retirement four years ago.

Dr. Charles Nelson Miller died at his home in German Valley, N. J., on January 14 of nephritis, aged forty-three years. Dr. Miller was a graduate of the Bellevue Hospital Medical College in the class of 1883, and an active member of the Morris District (N. J.) Medical Society and the Tri-County (N. J.) Medical Society.

Dr. William B. Neftel of this city died on January 20. He was born in Riga in 1830 and received his medical education in St. Petersburg. Dr. Neftel, in the Crimean campaign, was surgeon in the Russian army. In 1865 he came to the United States.

Dr. William Hillhouse of New Haven died on January 21 at the age of eighty-six years. He was graduated from the New York University Medical School in 1845. Dr. Hillhouse was the oldest living holder of a Yale honorary degree, it having been conferred in 1849 because of gifts to the university and in recognition of his high mathematical ability. He was the inventor of the old-fashioned trapdoor gallows used for years in Connecticut.

Dr. Abbie Cutler Tyler of Washington, D. C., died on January 6, at Warren, Mass., at the age of eighty years. Dr. Tyler was graduated in 1873 from the New England Woman's Medical College in Boston, and began her professional life in Waukegan, Ill. She went to Washington about twenty-five years ago and had since then practised there continuously.

Dr. W. B. Stoner, of Sunbury, Pa., died at Clifton Springs, N. Y., on January 9. He was graduated from the Kentucky School of Medicine in the class of 1892.

Dr. Hiram N. Rucker, Superintendent of the Masonic Home at Decoto, Alameda County, Cal., met with a terrible death on the night of December 13. During the evening, he had attended a meeting of the board of directors of the home, at San Francisco, and took the late train for Decoto. A short time after the train had passed the station, his mangled body was found upon the track beyond the stopping place. He had doubtless overlooked the stop and attemped to alight after the train was in motion. Dr. Rucker was sixty-one years old, a native of Missouri, and leaves a wife and daughter.

Dr. Richard L. Kendall, a prominent homeopathist of Aurora, Ill., died at San Diego, Cal., January 1, a few days after his arrival, in search of health.

Dr. Robert W. Steger of New York City died suddenly on January 10 at the age of forty-eight years. Dr. Steger was a native of Alabama and was graduated from the College of Physicians and Surgeons of New York in 1878. In a letter found after his death he directed that his body be given to that institution for dissection.

Dr. Selwyn A. Russell of Poughkeepsie, N. Y., died on January 11 after a short illness. Dr. Russell was a graduate of the Albany Medical College' class of 1877, and was for two years resident physician there. At different periods he had served on the medical staffs of the Utica and Poughkeepsie hospitals.

Correspondence.

PROTEST AGAINST ACCEPTING THE "PRINCIPLES OF MEDICAL ETHICS" OF THE AMERICAN MEDICAL ASSOCIATION BY THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

To the Editor of the Medical Record:

Sir:—On the first of October, 1905, a circular was issued to all members in good standing of the Medical Society of the State of New York and the New York State Medical Association, which contained the following: "Section 7. It is further covenanted and agreed by the parties hereto that as soon as practicable after the entry of an order for the consolidation of the corporations the following proposition shall be submitted by referendum to the vote of the members of the Society, namely:—'That the Principles of Medical Ethics of the American Medical Association, being suggestive and advisory, shall be the guide for members in their relations to each other and to the public.'"

The final consolidation of these two societies was perfected on December 9, 1905, and it is fair to presume that at the coming meeting of the Medical Society of the State of New York the matter will be submitted to the vote of the Society; and I take this opportunity to present to my fellow members of the Medical Society of the State of New York my reasons why this Medical Society should decline to be guided by or to accept the so-called "Principles of Ethics" of the American Medical Association. My reasons are as follows:

First: *Because these Principles are trivial and childish.* It seems hardly necessary that physicians should be instructed to be ever ready to obey the call of the sick and injured, or to be mindful of the character of their mission and the responsibilities they must incur in the discharge of momentous duties; or that they should be bidden never to forget that the comfort, the health, and the lives of those entrusted to their care depend on skill, attention, and fidelity. It seems absurd that they should be lectured upon their deportment, or that they should be told to unite tenderness, cheerfulness, and firmness, and thus inspire all sufferers with gratitude, respect, and confidence.

It would go without saying that patients committed to the care of a physician should be treated with attention and humanity and that reasonable indulgence should be granted to the caprices of the sick, or that the physician should strictly observe secrecy and delicacy; for medical men who require to be thus tutored in the first duties of their profession are unfitted to assume the responsibilities of their calling. Especially is the obligation of secrecy imposed upon physicians, for it is stated to be so great that they have been protected in its observance by courts of justice. As a matter of fact, this protection is not one extended to physicians, but to the patients, and on this point I shall have something to say later on.

When the Principles come to treat of the duties for the support of professional character, the medical profession is apprised of the obligation under which County Medical Societies are placed by affiliating themselves with their respective State Associations, and these in turn with the American Medical Association; and the profession furthermore is adjured that there is no profession from the members of which greater purity and a higher standard of moral excellence is required than the medical; and to attain such eminence is the duty every physician owes to the profession and to patients. It is due to the patients, as without it their respect and confidence cannot be commanded; and to the profession, because no scientific attainments can compensate for the want of correct moral principles.

Without stopping to argue as to the correctness of this statement, I should like to ask if such inane drivel is really required to instruct physicians as to their duties to each other in support of professional character. It seems to me to be among those things that physicians are grounded in before they are allowed to qualify for practice, and that it should be as unnecessary to inculcate these principles in a code of ethics as it would be to instruct physicians that they should not steal, that they should not commit adultery, and that they should not bear false witness against their neighbor.

There are scattered throughout this little pamphlet other absurdities which might be criticised, but I think I have shown enough evidence to prove my contention that these principles are trivial and childish, and I shall therefore pass to the next objection: that *these Principles are negative in character;* and I shall ask your attention to the Second Chapter, Article I, Section 7, which reads that "it is incompatible with honorable standing in the profession to resort to public advertisement or private cards inviting the attention of patients affected with particular diseases; to promise radical cures; to publish cases or operations in the daily prints, or to suffer such publications to be made; to invite laymen (other than relatives who may desire to be at hand) to be present at operations; to boast of cures and remedies; to adduce certificates of skill and success; or to employ any of the other methods of charlatans."

It is a time-honored belief in the medical profession that the code forbids physicians to advertise, but it will be seen on reading the above section that such is not the case. Physicians are instructed that it is incompatible with honorable standing to publicly advertise, *only when their advertisements invite the attention of persons affected with particular diseases;* in other words, it would be perfectly proper for a physician to insert a card in the public prints giving his name, his address, and his consultation hours. As regards the private cards, I have seen the cards of presumably reputable physicians which stated that they confined themselves to the treatment of particular diseases—to wit., diseases of the eye and ear, or diseases of the throat—and I frankly confess that I fail to see why they are incompatible with honorable standing, for certainly it is oftentimes of great service to know that a man devotes himself more particularly to, or claims to have a special knowledge of, a certain class of diseases. But while, after all, this is entirely a matter of taste, I admit that to promise radical cures, to boast of cures, or to adduce certificates of skill are all in bad form and much better avoided, as are also the business methods which are sometimes employed by physicians in paying or offering to pay commissions to persons who may recommend to them patients requiring general or special treatment, or surgical operations, or to solicit or to receive such commissions—and yet we all know of cases in which it has been done.

In the first and second sections of the third chapter, physicians are instructed that they should be ready to cooperate with the proper authorities in the administration and the observance of sanitary laws and regulations, and that it is the province of physicians to enlighten the public in regard to quarantine regulations; to the location, arrangement, and dietetics of hospitals, asylums, schools, prisons, and special institutions, in regard to measures for the prevention of epidemic diseases, etc.—but nothing is said or suggested as to how this instruction and cooperation should be carried out or to whom this duty should be delegated. It certainly is not for the honor and dignity or the interests of the profession to have new methods of treating diseases exploited in the public prints, as has been done within recent times, where the opinions advanced have been crude and ridiculous, and where the premises upon which these newspaper statements were based have been entirely insufficient; but I fail to understand why instruction given by competent authority should be frowned upon, even if the information is conveyed in the public prints.

The third objection I have is: that *these Principles are impertinent and intrusive;* and in support of this contention I invite attention to the fourth and eighth sections of the first chapter, the former of which reads that "frequent visits to the sick are often requisite, since they enable physicians to arrive at a more perfect knowledge of the disease and to meet promptly every change which may occur. Unnecessary visits are to be avoided, as they give undue anxiety to the patient," and the latter, that "the opportunity which a physician has of promoting and strengthening good resolutions of patients suffering under the consequences of evil conduct ought never to be neglected."

Visiting the sick, I maintain, should be left entirely to the discretion of the physician, and it is nobody's business to instruct him whether he should call frequently or infrequently, nor to invite his attention to the avoidance of unnecessary visits. This admonition seems to me an impertinence which does not come within the province of any code of ethics to advise about; and as to the physician's assuming the rôle of preacher and promoting and strengthening the good resolution of patients, I believe, from some experiences I have had—not only personal, but impersonal—that such admonition is usually resented by the patients as impudence. At any rate, it seems to me that all this ethical twaddle is better suited to the nursery or Sunday-school than to a code of ethics for grown-up men who presumably have some sense of decency and some knowledge of the proprieties of daily life and conduct.

Then again, in Chapter II, Article 1, Section 2, the physician is adjured, among other things, "to honor the fraternity as a body . . . and that he should entertain a due respect for those seniors who by their labors have contributed to its advancement." Now the fraternity as a body will be honored if honor is due it, and no instruction to honor it as a body will receive the slightest attention

if medical men themselves do not behave in such a manner as to command respect; nor should due respect be paid to those seniors who, notwithstanding their labors, show by their private life that they are not entitled to respect. On those matters each man will judge for himself, and he will wear the crown who most deserves it, irrespective of these paternal warnings which the American Medical Association seems to think necessary to inculcate in the minds of medical professional men.

Now, in the eighth section of this same article, after other advice which I think may be open to fair criticism, we find: "It is equally derogatory to the professional character for physicians to hold patents for any surgical instrument or medicine, and to accept rebates on prescriptions or surgical appliances, to assist unqualified persons to evade the legal restrictions governing the practice of medicine, or to dispense or permit the use of secret medicines: . . . it is highly reprehensible for physicians to give certificates attesting the efficacy of secret medicines or other substances used therapeutically."

As regards the first section, I cannot for the life of me see why a physician or surgeon should not be entitled to reap pecuniary benefit from a surgical invention of his own. In every other walk of life it is recognized that a man is entitled to such benefit, and I can see no good reason why the doctor should not also be granted a similar privilege. As it is, all the advantage goes to the instrument-maker, a man who, goodness knows, charges sufficiently for whatever work he does for both surgeon and patient. The surgeon devises the instrument and the instrument-maker reaps the pecuniary advantage, and the unfortunate surgeon gets nothing. It would be just as sensible to deny a man's right of holding a copyright on his book as to say that he shall not hold a patent on his own invention. It seems to me one of those instances of an impertinent interference with the rights of another. To hold a patent for a medicine is a different thing, for there is no invention nor anything which is peculiarly a part of the man himself. Of course it is improper to assist unqualified persons to evade the legal restrictions governing the practice of medicine, and yet I was somewhat amused at a recent meeting of the society which is a strenuous upholder of the code in this city to hear the name of a medical man suggested for membership who, it was admitted, had not complied with the laws of the State relating to the registration of physicians and that this infraction was known to the committee which reported his name. There was a slight demur as to passing the man and many members of the society were in favor of admitting him because—if I remember rightly—he was a good fellow; but I am happy to say, for the sake of consistence with the code of ethics, one member so strongly objected to the candidate's admission that the name was referred to the committee again with instructions to call the attention of the candidate to his delinquency. I only instance this to show how very lightly any of these obligations sit upon the average medical man when he wants something done that he has set his heart upon.

In Article 2 of that same chapter, in the second section, is a clause which reads that "all practising physicians and their immediate family dependents are entitled to the gratuitous services of any one or more of the physicians residing near." I think that a matter which could with propriety be left in the hands of the attending surgeon or physician himself, but I should like to ask if medical men would consider that the homeopath, the eclectic, the osteopath, and all of that tribe, are also entitled to gratuitous services, and whether the average medical man would feel disposed to extend such professional courtesy to them; for, mark you, it reads "all practising physicians," not "all legally qualified physicians." More than that, some doctors are able to pay and do not wish to be placed under an obligation, and I do not think that the attending physician has any business to impose such obligation if it is not desired; and, moreover, I would like to ask if any one has the right to take up the time or to call upon the skill of a physician for a private disease of any kind merely because he chances to be a doctor. This section seems to me therefore not only an impertinent interference with personal action, but anabsurdity on the face of it

I might go on and multiply instances, but if I did this letter would be spun out to interminable length, and I shall therefore close with my fourth objection, to wit: *That these Principles of Medical Ethics are deceitful and hypocritical.* They start off in the very preface with the statement that large discretionary powers are left to the respective state societies to form such codes and establish such rules for the professional conduct of their members as they may consider proper, which upon its face would seem to leave entire freedom to these different societies to formulate their own codes and rules; but mark well what follows: "Provided, of course, that there shall be no infringement of the established principles of this Association." In other words, while it seems to leave a free hand to the societies to establish their own rules, these rules must be in conformity to these principles, which is tantamount to enforcing them. Would it not have been more honest to have stated that these different state societies *must* adopt the ethical principles of this Association?

In addition, in the first chapter,—almost throughout the whole of it—the various sections which treat of the conduct of physicians to their patients bear the mark of cant to such a degree that it is difficult to read it without a feeling of profound contempt, and I should have supposed that Messrs. Mawworm and Chadband had between them concocted these rules, so replete are they with the unctuous cant and hypocrisy which characterized those two apostles of humbug.

In Article Third of this same chapter, in the second section, we read that "consultations should be promoted in difficult cases, as they contribute to confidence and enlarged views of practice." Now that is rank nonsense and deceit. Consultations certainly of the present day, so far as I have been able to observe, oftentimes do not contribute confidence nor do they enlarge views of practice, and many consultations are called for, not because the attending physician wants more light or instruction upon the case, but because the patient's family or friends have heard of the celebrated Dr. X. and feel that their friend cannot get well without his advice and cooperation, and therefore they insist that X. shall be called. Another objection to consultations which I have heard from juniors in the profession, is that after a consultation they see no more of the patient, and the feeling is by no means uncommon—I do not pretend to say whether it is right or wrong—among the younger practitioners of medicine that the senior is not above taking an unfair advantage and either retaining the patient himself or sending him to some one of his assistants, entirely regardless of the rights of the attending physician.

In Section Five of that same article the physician is adjured that "in consultations no insincerity, rivalry, or envy should be indulged; candor, probity, and all due respect should be observed toward the physician in charge of the case." "So mote it be;" but envy, hatred, malice, and all uncharitableness will be unknown things in this world only when the millennium occurs. We believe that the most sublime goodness should dictate our conduct to each other, but we also know it does not; hence it is probable that these Principles of Ethics, like the teachings of the Sermon on the Mount, will remain "only an iridescent dream."

In the earlier part of this letter I adverted to the obligation of secrecy imposed upon physicians, in which the code of ethics declares physicians have been protected in its observance by courts of justice. In this particular the Principles of Medical Ethics talks either without knowledge of facts or else with willful intent to deceive, for this is no protection designed for the doctor but for the patient, and courts of law have not protected physicians in the observance of secrecy but have *imposed* secrecy upon them, oftentimes to their detriment, for the *protection of the patient;* so that as this clause stands, I repeat, it shows either gross ignorance or something very like deliberate deception.

While I have by no means exhausted the many points which could be criticised in the Principles of Medical Ethics, I must forbear, but not before I have said a word in parting. Those of us who can "hark" back to twenty odd years ago when the so-called code fight took place in the State Society, will remember that the main grievance against the code was that it was "an impertinent interference with the rights of others." The Medical Society of the State of New York deemed itself amply able to look after the manners and morals of its medical practitioners and it required no interference and no kindergarten instruction from the American Medical Association. After the old code had been practically abolished in this State, a delegate was sent from the State Medical Society to the American Medical Association to explain the Society's action—a man whose name was known and honored not only in his own country but elsewhere throughout the world. When he appeared before the Association he was treated with contumely and denied the right granted the meanest criminal in this country—the right of a hearing; and we can also remember the kindly and fraternal, the amiable and dignified manner in which New York physicians were assailed as "sighing for the fleshpots of Egypt," and "aching for consultations with homeopaths or any other irregular."

Of course the State Society has not since been represented in the councils of the American Medical Association, but notwithstanding that fact the Medical Society of this State has not suffered. On the contrary, it has done so well in many things, not only in keeping up the honor

and dignity of the profession in both its ethical and scientific aspects, but it has instituted so many good reforms—such as the registry of physicians, state examinations, and the like—that the American Medical Association has expressed a desire to have the State Society come back; —to which I say Amen, provided that no conditions are imposed upon the Medical Society of the State of New York for readmission, no code, and no principles of ethics. New York can manage her own affairs and she will accept no dictation nor interference from any other society in this land. The American Medical Association pretends to be the *arbiter morum* of the medical profession in this country. It numbers officially 21,000.* The medical profession in this country numbers 118,000.† Does it not seem rather an assumption of arrogance that a small proportion of the medical men of this country should dictate to their fellows how they shall comport themselves professionally in public or in private? I confess it seems so to me, particularly as the proud boast of this country has been that the majority rules. Here we reverse it and make the minority rule.

I have never been able to share the enthusiasm of some of my medical brethren for the code of ethics. It has always struck me as being a rank humbug, good enough when it first began—as I understand it did before it blossomed out into a code of ethics—as the advice of a medical father to a medical son. It conveys sentiments and ideas which a father might very well impart to a son but which are entirely inappropriate as rules for the governance of a profession of grown men who are supposed to have put away childish things. Indeed I have never been able to regard the Code or its offspring, the Principles, as anything but "as sounding brass or a tinkling cymbal."

F. R. Sturgis, M.D.

16 West Thirty-second Street,
New York City.

THE FEE QUESTION.

To the Editor of the Medical Record:

Sir:—I have read with interest the correspondence on "The Fee Question," in your issue of January 6, 1906, as presented by Dr. Robert T. Morris of New York. As a general practitioner I cannot help sympathizing with Mrs. C. when she writes, "but we feel you make us pay too dear for it," and admiring Drs. A. and B.

Undoubtedly had Richard McCurdy, the late president of the New York Mutual Life Insurance Co. written to Pres. McCall, of the New York Life Insurance Co., to Pres. Alexander, of the Equitable Insurance Co., and to Pres. Heyeman, of the Metropolitan Life Insurance Co., concerning the fairness and justice of his $150,000 salary, they would have written similarly as did these three surgeons, justifying the enormous salary by the size of the reserve fund, the number of policies in force, the aggregate amount of premiums annually received, etc. Undoubtedly they would have called attention to the possible tremendous loss by an error of judgment in making investments. Now, as a matter of fact, while insurance companies, as companies, carry tremendous financial responsibilities, the work gradually becomes more or less mechanical, a cog with cog, self-perpetuating, automatic, not wholly dependent upon the president, but on the united efforts and judgments of the heads of departments. Indeed President McCurdy showed a lamentable lack of knowledge concerning many large details of the business, which, if the success depended so tremendously on him, he should have known.

Similarly the knowledge, ability, and success of Dr. Morris are not entirely to his own credit, but are due largely to his opportunity and environment. His opportunity for large hospital practice by which to perfect himself, an opportunity that almost any practitioner would court, even at the cost of thousands of dollars per annum, is one example of his opportunity. The perfection of the operation for appendicitis was not the result of his work alone. It is due to the compilation of the efforts and ability of hosts of others.

Undoubtedly the operation was worth $1,000 to the patient, and many times that. But on this score he would owe it to many a mechanic, who by his efforts and ability have rendered travel safe, or other individuals who might have saved his life when in danger from an unlucky accident. The value of the services is largely dependent upon the gray matter expended and effort and expense used in attaining the ability to perform a piece of work. The fact that perchance some lawyer or life insurance president receives an exorbitant amount does not justify another lawyer of a physician to charge exorbitant fees.

Two wrongs do not make a right. True, it is that it costs more to live to-day than formerly and that a professional man of standing is obliged to maintain a high standard of living in order to maintain his position. But these truisms do not permit an unlimited charge.

Dr. M. states that fifteen years ago he would have been longer in doing an appendectomy and it would not have equaled the operation of to-day. True, but this advancement is not due wholly to him. If it is worth $5,000 to-day to do the operation, it was worth $25,000 then, if the measure is to be in any degree the amount of anxious care and effort expended. The method, as he describes it, was the best way then known. In other departments of life, improved mechanisms and time-savers, which lessen care and time, have cheapened the product.

The success of the operation of the present day is due more largely to the evolution of the technique than to the individual operator. To this improved technique many have contributed. Dr. M. to-day can do more operations in a day than formerly. On that particular day he did three other operations, besides, probably attending to office work during office hours. Taking all things into consideration his fees seem to me to be exorbitant. The difference between the general practitioner of equal ability and him is not the vast chasm as represented by the difference of the fees of the two. Dr. M. exceeds in one line, the general practitioner in another, equally high grade and as representative of ability, effort, and time given to perfection.

Such an attitude as manifested in Dr. M.'s communication tends to breed anarchistic and socialistic spirit. It is unfair to patients and brother practitioners. Surgeons of that kind should not be sustained by the general practitioner. Truly, as he states, "We are going through a transition stage . . . but the right is certain to prevail." This is true in matters medical as well as in the commercially inclined life insurance companies, Standard Oil, railroads, etc. Allow a living fee, yea, a generous fee, but not an outrageously exorbitant one.

Boston, Mass., January 11, 1906.

OUR LONDON LETTER.

(From Our Special Correspondent.)

EXTRAVAGANCE OF HOSPITAL MANAGERS—APPENDICITIS—HEALTH OF THE NAVY—CHILD LIFE IN LONDON—JOHN BURNS AND ANTIVACCINATION—SIR W. FOSTER, P.C.—THE MURDER OF DR. STEWART IN AFRICA—OBITUARY NOTE.

London, January 5, 1906.

I have several times referred to the extravagant expenditure in which hospital managers indulge with a light heart. They load their institutions with debt and on account of its extent claim assistance from the public. It has become a common proverb that a debt is a good advertisement. The absurdity of much of the costly outlay on improvements and extensions is becoming more recognized by thoughtful philanthropists as well as by some of the leading professional authorities. A forcible protest against it reaches me from Dublin *apropos* of a paper at the Royal Academy of Medicine by Dr. Hastings Tweedy, dealing with a series of 211 major operations he had performed in the Rotunda, which is, as we know, the great hospital for women and the chief school of obstetrics and gynecology in Ireland.

The cases included examples of all the usual run of gynecological operations and the series must be pronounced successful, but for the moment my concern is with the point mentioned above.

He said no failure could be traced to any defect in his operating room which was simple but adequate for all the requirements of aseptic surgery. In its very simplicity it is a crushing argument against the lavish expenditure so fashionable in the present day which is supplanting the modest workshop of the surgeon by an operating theater, which might serve as a dazzling advertisement for an electrical quack.

Dr. Tweedy met with support in this protest; Dr. Jellett agreed with him thoroughly and Dr. Horne also deprecated the tendency to expend enormous sums on the construction of operating theaters.

After this it is to be hoped there will be some searchings of heart among London hospital committees and that architects will learn that they must not regard these institutions as monuments to themselves.

It is not only in the charitable hospitals that extravagance has been growing. On a still larger scale the poor law authorities have been squandering money on elaborate buildings until one of them has been boasting of having erected the finest infirmary for paupers in the world. But the boast has attracted the attention of the press to these "palaces for paupers" and some wholesome advice has been offered to rate-payers who are being urged to cast

aside their foolish apathy and insist on economy in municipal expenditure.

The Balneological and Climatological Society has lately discussed the part played by their branch of medicine in regard to the prevention of appendicitis. Dr. Tyson began with a practical paper in which he expressed the belief that the most common cause of the disease is a lodgment of undigested matter or fecal masses in the bowel. He had himself gone through two attacks, both of which he traced to constitpation and it is the experience of many patients that the bowels were confined just before the attack. The older doctors certainly insisted much more on a regular evacuation than many do in the present day. Dr. Tyson said that dosing with salts and black draughts had more to do with the prevention of toxemic intestinal conditions than we are ready to admit. In those far-off days there was more time for study and observation of symptoms, and it was found that free stools kept the head clear and the body cool. Now there are many conditions which have increased of late which are more or less associated with constipation, such as oral sepsis, excessive or unnatural eating, as in modern hotels, unsuitable food, alcoholism, weakened abdominal muscles, and bad methods of defecation. The subject of oral sepsis was commended to the attention of our dental brethren, that of overeating was enforced, especially meat, game and ices, while irregularity of meals and bad cooking were held responsible for much disturbance of the alimentary function. With regard to the special part played by balneology Dr. Tyson said the continental custom of "water drinking" periodically must have a beneficial effect and we possess at home a number of spas where this treatment can be just as well carried out. Such regular washings out of the intestinal canal would do much to prevent many cases of colitis and appendicitis. There is a tendency to ignore treatment at the early stage, still more prevention, and yet much good can be done.

In the discussion that followed Dr. Symes Thompson held that disinfection and lubrication of the intestinal tract were the essentials of prevention. Salol, he thought, secured the first, but in compressed form was untrustworthy. He did not explain how its insolubility could be overcome but proposed to suspend it in petroleum emulsion. Fluid vaseline in dessertspoonful doses would keep up regular action without purging. Dr. Sandwith said the disease was not so common among colored as white races and he attributed this to the cahe to avoid constipation or hurrying over meals—still more, perhaps to efficient mastication. Dr. B. Thorne attributed the disease to habitual toxicity of the intestinal contents, chiefly traceable to catarrh leading to fermentative decomposition which throws on the cecum—the disinfecting chamber of the bowels—more work than it can do. He regarded castor oil as the best disinfectant and bactericidal purgative. Dr. P. G. Lewis also regarded sepsis as the most frequent cause and said people must be taught what to eat and how to eat, especially the importance of thorough mastication. Dr. Leonard Williams agreed as to septicity but thought there were causes additional to catarrh. The excessive amount of meat consumed of late might account for the increase of the disease for it had been observed that increase corresponded with the lower price of meat. Another factor was the extra work thrown on the bowel by neglect of other emunctories. He had no doubt much of the work of the skin was thrown on the bowel. Persons with active skins did not often get attacked with appendicitis. He thought wearing flannel next the skin an unscientific and even ridiculous custom.

The Blue Book on the Health of the Navy was issued on Saturday and the report is very satisfactory. With a personel increased by 7,440 as compared with the previous year, the statistics show decreases in the ratios of cases, invalidings and deaths as compared with the average of the last seven years. The ratio of cases per 1,000 of the force shows a reduction on all stations except the Pacific as compared with the septennial average. The invaliding ratio is 22.7 per 1,000 and shows a decrease of 7.28 compared with the septennial period. The death ratio per 1,000 was 4.45, a decrease of 1.01. The total number of deaths was 493, of which 348 were from disease and 145 from injury.

In a report of the County Council Education Committee issued on Tuesday the medical officer, Dr. Kerr, deals with the physical conditions of child life in London, especially in relation to mental activity and educational fitness. Increasing solicitude is reported as to personal cleanliness of the children attending elementary schools. A large part of the report refers to infectious diseases in relation to school attendance. With regard to underfeeding it is stated that it is "impossible to attain an opinion of any scientific value without the expenditure of much time and money on observations of the physique of sufficient children to establish standards."

The new President of the Local Government Board, Mr. John Burns, has stated that personally he has always been opposed to vaccination and will do his best in the direction of his private views. This is the official who is to have the administration of the vaccination arts while the new government lasts. It is not a pleasant prospect for sanatoriums.

Sir Walter Foster has been made a Privy Councillor.

Further details have arrived at Liverpool of the murder of Dr. Stewart. It seems on returning from an expedition he went somewhat in advance of his carriers and missed his way and got into a hostile village. The carriers found his bicycle, and on a further search portions of a body, which they identified. The appearances indicated that the body had been partially eaten. The village is only two days march from Calabar but the natives are known to indulge in cannibalistic orgies when they think they can escape detection.

Mr. T. Platt, J.P., consulting surgeon to the Oldham Infirmary, died on the 29th inst., aged 73. He had held many offices in the town where he was the senior surgeon and had practised between forty and fifty years. He was made a justice of the peace in 1877.

Mr. T. C. Langdon, consulting surgeon to the Royal Hunts County Hospital died on the 18th inst. Though his health had failed of late he kept to his work almost to the last. He was Medical Officer of Health for Winchester, superintendent of the hospital for infectious diseases and held other posts in the city, in which he practised for more than forty years.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 8, 1906.

Open-Air Treatment of Bone Tuberculosis.—E. H. Bradford notes the experience of patients treated at the Wellesley (Mass.) Convalescent Home, and appends brief notes of thirty cases permanently cured. In this institution a large number of children are placed in shacks with free opening to the outer air, and it is kept open the year round. The author states that experience seems to have taught those who have had the direction and care of these cases that in our climate and environment a situation in the interior, if well selected, is, on the whole, more useful during all the months of the year than a sea-coast site. The sea-side sanatoria in Europe and in our country have proven their usefulness, but it must be remembered that the sea coasts in Europe present a different climate from that which in the winter surrounds the bleak coast of New England. Most of the patients had been previously treated in a well-ordered hospital but the marked gains in weight and increase in hemoglobin following their removal to the open-air environment are very striking.

What is the Relation Between Human and Bovine Tuberculosis, and How Does It Affect Inmates of Public Institutions.—Theobald Smith notes that investigations along the lines of relationship between human and bovine tuberculosis have firmly established two facts: 1. The conception of two types of mammalian tubercle bacilli, a bovine and a human type and 2. the occasional presence of the bovine type in cases of human tuberculosis. He is not willing to admit the validity of the evidence tending to show the transformation of the bovine into the human bacillus in the human body though granting that certain changes may occur as manifested by a reduction of virulence. The bovine bacillus has been found almost exclusively in children under ten years of age. Phthisis and other forms of tuberculosis in adults are, so far as we know, almost wholly of human origin. In institutions in which children are cared for, the source of the milk should receive careful attention and herds belonging to the institution should be free from any traces of this disease. In institutions harboring adults there need be less anxiety on this point, and if all animals of reduced vitality or whose udders are not above suspicion are eliminated, the danger of infection may be regarded as exceedingly small. This standpoint is based upon the following well-established facts: (1) With few exceptions, cattle reacting to tuberculin are in an early or latent stage of the disease, during which tubercle bacilli are not excreted in the milk. (2) When tuberculosis becomes generalized, which frequently happens after parturition, and the udder and uterus become affected, physical examination and microscopic examination of the secretions should detect it. To these we may add that it is highly probable that we can successfully resist an occasional tubercle bacillus, and that most of us, at one time or another, have ingested without harm a few bacilli in milk or butter. It is equally probable that our

resistance may give way at an unguarded moment when our alimentary tract is being daily flooded with bacilli from a tuberculous udder.

The Suppression of Tuberculosis in Our Dairy Herds.—A. Peters comments on the spasmodic and sporadic efforts often made to keep herds free from tuberculosis. What we need is a rational plan, rigidly adhered to. With tuberculin as a diagnostic agent it is perfectly possible to eliminate diseased and infected animals from a herd, and with thorough disinfection and the purchase only of tested animals with semi-annual tests of all the animals, a healthy herd may be maintained. A practical method of immunization is greatly to be desired. Stable hygiene should receive the closest attention, but this alone is not sufficient.

New York Medical Journal, January 20, 1906.

The Maintenance of Asepsis.—D. H. Craig expresses the belief that antiseptics with the possible exception of sixty per cent. acohol, should be absolutely forsworn in the disinfection of living tissues and in the operating room. Corrosive sublimate requires time for the penetration of the capsule of pathogenic organisms. As a mere rinsing solution it is no better than sterile water. Moreover it may irritate delicate tissues. He mentions several incidents occurring in the course of operations, which completely nullified elaborate aseptic precautions previously made. None of these occurrences may have done, the author admits, any serious harm to the patients in question, but they were full of possibilities for evil, and if left uncorrected would have placed an additional tax upon the patient's powers of resistance. He moreover declares his belief that, since the establishment and maintenance of absolute asepsis are impossible to living tissues, the so-called "reaction" temperature seen on the postoperative charts of surgical patients is in the vast majority of all cases, especially those in which no demonstrable degree of surgical shock obtains, neither more nor less than an index of the amount or dose of infectious material introduced. Consequently surgeons having learned how to acquire a practical degree of sterility in connection with operations should learn how to maintain that sterility to the very end of its need. They must acquire the aseptic conscience.

Some of the Uses of Pelvic Massage.—J. T. Johnson quotes from several of the current text-books on the subject of pelvic massage and states that his own experience with this procedure has been mostly in the non-operative treatment of uterine displacements. The displacements themselves cause, in his opinion, very little trouble, but the complicating effusions, exudations, adhesions, and inflammations are potent for evil. Acute inflammations, infections, the presence of pus, malignancy and ectopic pregnancy contraindicate pelvic massage, but we do have many distressing retrodisplacements unaccompanied by any of the above-mentioned associated contraindications, but complicated still by those other associated conditions which are not included among the contraindications. In those cases in which one possesses the expert skill to differentiate the safe from the unsafe conditions, pelvic massage can be relied upon to restore abnormal to normal states when intelligently and honestly carried out by one fully understanding its details. The author considers that surgery for the relief of displacement has been overdone, declaring that the number of operations devised exceeds that of Heinz's "57 varieties," and believes that there is a promising future for pelvic massage.

The Therapeutical and Prognostic Value of Occult Hemorrhage in the Stools.—J. D. Steele discusses this question with special reference to gastric ulcer in which malady, however, blood does not always pass in the stools. Its presence, however, is always a confirmation of a diagnosis made on other grounds, and it is of special value, first, in the differentiation of true ulcer from stomach pain due to neurosis, especially when the latter is accompanied by hyperacidity; and second, in the recognition of chronic gastric ulcer. The test for occult blood can be used to control and determine the length of the various periods of medical treatment of ulcer. The bleeding should stop within a week after the patient is placed on a milk diet and rest in bed. As soon as blood disappears from the stools, provided the other symptoms are favorable, the diet may be increased. If bleeding recurs during the period of increase in diet, it indicates that the change is being made too rapidly. Persistent recurrence of hemorrhage when the change from liquid to solid food has been tried a number of times would indicate that the ulcer will not heal under medical treatment, and that surgical intervention is called for. The author's final conclusions are as follows: The conditions in which the test for occult blood in the feces will be of prognostic and therapeutical value in the course of gastric ulcer are as follows: First, to determine the length of the various periods of the medical treatment of ulcer; second, to detect the tendency to bleeding during the course of gastric ulcer and by appropriate medical and surgical measures to anticipate and prevent serious hemorrhage; third, to determine when the medical treatment may have failed and surgical treatment is indicated; fourth, perhaps the test may prove helpful in certain circumstances in detecting the development of a cancer upon the floor of an ulcer.

Migration of Helminths.—H. Page operated upon a Filipino native for suspected appendicitis. The patient brought to him from a distance was suffering from severe abdominal pains. The whole belly wall was swollen and indurated, but was not particularly tender upon pressure. An ill defined large lump was felt over the region of the appendix, and this fact suggested appendicitis, though a definite diagnosis was not made. The incision through the abdominal wall passed through honeycomb granulation tissue to a depth of several inches. At the bottom of the wound there was eventually removed a great number of long ascarides, which were in several instances coiled in large cavities. This made the operator fear lest he had opened an intestine, and he put a hurried end to the operation. Administration of hematoxylon showed that there was no fecal fistula, and santonin cleared the bowel of a mass of worms, while for many days from the tissues of the abdominal wound, worms were extracted. The patient finally recovered.

American Medicine, January 20, 1906.

Acute Osteomyelitis.—Emil King emphasizes the necessity for early diagnosis. Cases running an atypical course, or not responding properly to treatment, should put the physician on his guard that he may revise his diagnosis. Greater care should be exercised in the examination of patients. The early diagnosis of osteomyelitis is not always easy, but can usually be made by bringing to aid all modern methods, such as a blood count and the Roentgen ray. Early proper treatment will save much suffering, possibly lifelong crippling, and perhaps life itself.

Etiology, Symptomatology, and Treatment of Anal Fissure.—Herman A. Bray states the most characteristic symptoms of anal fissure are: pain or irritation of the anus and paroxysmal contraction of the sphincters. While these symptoms may be considered as pathognomonic of the disease, without a local examination, comprising inspection and a digital exploration, it is not possible to reach a correct conclusion. Treatment may be either palliative or operative. The former is sufficient in most cases. It consists of measures for preventing constipation, observation of local cleanliness, and local applications to the ulcer. The method of operation employed by Dr. Bray is divulsion with incision, trimming at the same time the indurated margin of the wound, and curetting the base. The bowels should be kept confined for three days, and after this time daily movements are secured by laxatives. The ulcer usually heals in about two weeks.

Diagnosis of Incipient Genitourinary Tuberculosis.—G. Frank Lydston emphasizes the fact that greater care in diagnostic methods will enable us to discover genitourinary tuberculosis in its incipiency much more frequently than is ordinarily supposed. He reports a number of cases showing that after every other test failed inoculation of a guinea pig with the urine was reported to with the result that in each case the animal developed distinct tuberculosis.

Ectopic Gestation.—William H. Randle believes that many patients die each year of so-called heart disease and other causes, when in reality the death is due to internal hemorrhage from ectopic gestation. He discusses the pathology symptoms, and diagnosis of this condition. In cases of doubtful diagnosis a small vaginal incision may be made through the posterior vaginal vault, when the escape of free blood will verify the diagnosis. The treatment is invariably surgical. As little anesthesia should be used as possible, and stimulation should be withheld until the bleeding point is secured. When the abdominal incision is made no attention should be paid to the enormous quantity of blood that usually gushes forth, but the surgeon should place his hand directly on the ruptured tube and clamp the bleeding parts. After this vigorous stimulation may be employed. The blood clots may be rapidly ladled out and the abdominal cavity flushed with a large quantity of sterile saline solution. A quantity of this fluid may be allowed to remain in the pelvic cavity. Drainage is rarely necessary, in fact it is detrimental. In all cases in which a hematocele has formed, a vaginal incision may be made with the evacuation of the clots which lie in large quantities in the pelvic cavity; but the patient should be prepared for the abdominal operation should it prove necessary because of the recurrence of hemorrhage.

Diabetic Purpura.—C. H. Lefcowitch reports the coexistence of purpura and alimentary glycosuria in a boy of 3. The patient was nervous and suffered from enuresis and a stomatitis of moderate severity. His appetite was poor but his general nutrition was fair. After two months' treatment, largely dietetic, the boy apparently made a complete recovery. One year later the patient presented the typical aspect of a true diabetes mellitus, but no symptoms of purpura. After nine months constant attention under the family physician, the boy remains comfortably healthy while under a judicious diet. Lefcowitch emphasizes the importance of urinary examinations in the infant and child in making a diagnosis and in the study of metabolism.

Journal of the American Medical Association, January 20, 1906.

Rhythmic Sounds in the Alimentary Canal.—W. B. Cannon describes and differentiates the various sounds produced under normal conditions in the alimentary canal. Their most characteristic feature is their rhythmicity, over the stomach rhythmic persistaltic waves pass in regular succession; in the small intestine the most usual activity is the rhythmic segmentation of the food; and in the large intestine rhythmic antiperistaltic waves follow each other at short intervals in the ascending colon toward the cecum. Gas mixed with the food favors the production of these sounds and when air-containing food is taken, and frequently after an ordinary meal, rhythmic sounds can be heard over the pyloric end of the stomach, and later over the small intestine. The gastric sounds are best heard after a bountiful meal, say an hour after dinner and with the subject lying on the left side with the pyloric end of the stomach uppermost. The disk of the stethoscope should be placed near the end of the eighth rib on the right side. The sounds heard are usually loud, rattling, explosive, and of characteristic quality, sometimes lasting several seconds. They recur at intervals varying in the neighborhood of every 20 seconds and are sometimes strikingly regular. During the height of digestion there is usually a confusion of abdominal sounds, especially over the right lower quadrant of the abdomen. It is, therefore, better to listen first in the night, or better still, an hour or so after waking in the morning before breakfast. The stomach is then quiet, and with the disk of the stethoscope over the lower left quadrant the active part of the large intestine is avoided. The rhythmic sounds of the small intestine then heard are quite different from those of the stomach. They vary in quality, sometimes a soft, muffled rumble, sometimes fine crepitation, and sometimes a group of little rattling explosions. There are, however, three distinctive features. There are, first, the slow crescendo followed by a diminuendo in the sound, so that each sound lasts two or three seconds or more; second, the persistence of the rhythm in one place; and, third, the distinctive rate, the usual interval being every seven or eight seconds. In the morning, after a full dinner the night before, Cannon has heard these sounds continue an hour and a half without interruption, but they can also be heard at other times, and even in the midst of active digestion. The variations of these sounds in pathologic conditions and the sounds of the large intestine have not yet been studied, and the bearings of these studies on clinical medicine are yet unknown. Cannon suggests that the method may be used in some cases to differentiate "motor insufficiency" due to imperfect peristalsis from that caused by pyloric obstruction.

Amaurotic Family Idiocy.—M. Frank reports briefly a case of this condition, describes the characteristic fundus changes, and reviews the literature regarding them. The characteristic ocular symptoms which remain unaltered through the course of the disease, consist in a nebulous grayish white area surrounding the macula about three times the size of the disc, somewhat oval in shape, with the major axis horizontal, and gradually bending at the edges with the normal fundus. At its center, coinciding with the fovea but larger, is a clearly defined dark red or liver-colored spot. Surrounding this can be seen the tiny retinal vessels. Strabismus and nystagmus have been observed in some cases. There is no recorded regularity in the pupillary conditions. The other symptoms of the disease, the marasmus, the mental failure, and ultimate paralysis, together with the hereditary or family tendency are mentioned, together with the optic atrophy and blindness. Frank attributes the pathognomonic eye changes to swollen and degenerated ganglion cells rather than to an edema; the constancy of the phenomenon and the lack of veiling of the vessels are against edema. He summarizes the cases reported up to date, 54 in all, with 22 others referred to. Where race data were given the great majority are Jews. There have been 12 post mortems, and in 6 cases the eyes were microscopically examined.

The Actual Cautery in Leucorrhea.—G. L. Hunner describes his method of treating leucorrhea by making deep radial incisions of the cervical tissues by means of the cautery blade. With the patient in the dorsal or lithotomy position, a broad-bladed Sims speculum is introduced into the vagina, the anterior lip of the cervix is seized with a tenaculum, and the cervix is pulled down as near to the vulva as possible. The nurse works the cautery bulb with one hand, while she holds the speculum with the other, and the operator keeps the tenaculum in one hand and manages the cautery with the other. The strokes should be made one at a time, the cautery is removed from the vagina after each stroke as the patient feels the radiated heat on the vaginal walls. She must be warned not to move and she will feel no actual pain, unless there already exists a painful cervical scar, in which case Hunner uses preliminary cocain anesthesia by means of a tampon soaked with 20 per cent. cocain solution applied for ten minutes. The number and depth of the strokes vary with conditions present, but he usually gives six, ranging from 2 to 5 mm. in depth, and extending across the whole hypertrophied mucosa. The treatments are given once in three weeks and usually number from three to six. A sterile strip of gauze is left in the vagina against possible hemorrhage and the patient is instructed to withdraw it the following evening. If the bleeding is profuse she should go to bed. There is often a little hemorrhage after three or four days, and in one or two of his cases this was enough to alarm the patient. A daily douche is advised during the interval between treatments. So far as Hunner knows, there have been no bad after-effects as regards parturition. He emphasizes the importance of a correct diagnosis before treating any case of leucorrhea. If there is any suspicion of cancer, he advises an examination by a competent pathologist. In fresh gonorrheal cases he does not use the cautery or anything that can excite or extend a cervical infection. In chronic gonorrhea he does not persist too long with the cautery or cervical treatments, as there may be infection higher up, but cases not extending above the cervix may be considered curable. The quickest and best results are obtained in a cervical hypertrophy and eversion due to multiple childbirth. One advantage of the method is that it can be used in office practice and without anesthesia.

The Lancet, January 6, 1906.

A Case of Ochronosis.—F. M. Pope and A. E. Garrod report a case of this rare affection and tabulate ten other cases previously reported. Their own case is illustrated with a colored plate which shows very well the peculiar hue of the skin and also the microscopical findings of sections of skin and cartilage. The patient was a woman of forty-seven years, with a large ulcer on the leg, of twelve years' duration, and discoloration of the skin. The ulcer had been dressed continuously with carbolic acid solutions. The discoloration had existed for five years. The face was a dark brown. Inside the lips were blackish patches. The hands and ears were bluish and a small patch of similar hue existed on each conjunctiva about midway between the inner canthus and iris, when the iris was central. There were signs of a cavity at the apex of the right lung and the patient was much emaciated. Her mother had suffered from pulmonary tuberculosis. The urine was almost black in color; it gave a dark brown precipitate with liquor ferri perchloridi and a slight white precipitate with bromine water. No sugar or copper-reducing substance was present. The urine was not of the same color every day. Gangrene of the toes came on and the patient died in a few days from exhaustion, there having been no material change in the symptoms. Post mortem, the right lung had a dry cavity at the apex. The suprarenal bodies were hard and dark in color. The rib cartilages were stained bluish-black; the color was more marked in the central area than at the periphery. The cartilages of the ears were bluish-black. The intervertebral cartilages were not examined. The patches of pigment in the eyes were seen to be due to a deposit of pigment in the superficial layers of the sclerotic. The diagnosis from autopsy was tuberculosis of the lung and disease (Addison's) of the suprarenal bodies. The color of the urine was regarded as due to carboluria.

Operation on the Vestibule for the Relief of Vertigo.—The paper of R. Lake is illustrated with several anatomical diagrams showing the various steps to be followed in the operation referred to. The paper is in the main the report of one case with comments thereon, the patient being a woman of twenty-nine years, who had been for some time absolutely deaf on both sides. Several attacks of otitis media had occurred and the left ear was liable to relapse. Bilateral aural vertigo was pronounced, and when she walked she described, so to speak, a series of curves with the major tendency toward the left.

The operation is described in full, but space does not allow us to go into details. At the end of three weeks the woman was able to walk fairly straight, to go up and down stairs and to make all the usual motions of daily life without inconvenience. Only one side was operated on, but the results were so satisfactory that the patient expressed a desire for operation on the other side. A slight and transient facial paralysis remained. Lake notes in comparing this operation with the successful cases of intracranial division of the auditory nerve, that direct successful destruction of the posterior half of the membranous labyrinth would have been equally successful so far as vertigo is concerned; and what is of greater importance still, judging from experience thus far accumulated, the latter procedure is without danger to life.

Syphilis Following the Bite of a Human Being.—J. G. McNaughton reports the case of an adult woman who was bitten on the back of the hand by another woman. A sore formed subsequently at the place and required about six weeks for healing. About five weeks after the bite spots began to appear on her body and a little later her hair began to come out. When the patient was seen by the author the sore on the hand was quite healed, leaving a dark red scar of the size of a florin. The rash had quite disappeared but the woman was still suffering from condylomata. Her mouth showed several mucous patches, especially on the inner surface of the lips. In the larynx there was considerable infiltration of the interarytenoid region, with ulceration of one vocal cord. The patient is a widow; but there seemed to be no reason for believing that the disease had been contracted in any other way.

British Medical Journal, January 6, 1906.

Medical Aspects of Carcinoma of the Breast.—W. Osler notes that examination of the breast is often overlooked though extensive general lesions may be associated with a small latent carcinoma. There is one form of disease, carcinomatous mastitis, presenting the aspect of a diffuse, rapidly spreading inflammation, rather than of a new growth. Metastases may be intrathoracic, abdominal, cerebral, spinal and osseous. Illustrative cases are given with comments under each of these headings. Thus in one case, the initial symptoms were those of long standing neurasthenia, the onset being marked by pains in the back and legs and thought at first to be due to pleurisy. The peritoneum may be involved by direct extension and often there is a recurring carcinomatous ascites. Metastases in the liver are perhaps more frequent than in any other organ. Cerebral symptoms may be caused by involvement of either the cranial bones or of the brain itself. Symptoms of cerebral tumor may follow years after the removal of the breast or in a patient with an old atrophic scirrhus. The most common and most serious as entailing a maximum of suffering are lesions of the spine. These were present in ten out of a series of twenty-nine cases collected by the author. They are more common in the atrophic form of scirrhus and are often regarded as evidences of spinal cord affections. Actual kyphosis is rare. As a rule the pains are thoracic and lumbar, but may be at first sciatic, shooting down the legs. After the painful pressure symptoms there ensues pressure paraplegia, usually of the spastic type. Rarely there may be an involution of the metastases.

Lepra Ophthalmica. K. Grossman contributes an elaborate statistical paper describing cases examined at the leper hospital in Langarnec, Iceland, in 1901 and 1904. He notes that the disease is more rapid and more pernicious in the nodular form, both generally and as far as ophthalmic leprosy is concerned. From his personal observations he concludes that in lepra tuberosa the eyes become specifically affected in all cases, provided the patient lives long enough while in lepra anesthetica the eyes may remain unaffected if the nerves supplying the ocular adnexa remain free. The nodular form generally affects the adnexa first, supercilia and lids and attacks the eye itself later, though the eye may be affected when no nodular infiltration of the lids is present. When the eye itself is the seat of the leprous infiltration, or more accurately, when the episcleral tissue is attacked, the appearance is so characteristic that it cannot be mistaken for anything else. The pericorneal region of the sclera generally in a quarter or half its circumference becomes a pale, greyish-yellow color, quite anemic, and the slightly translucent and raised part looks like ivory. This infiltration has a tendency to spread, especially laterally, so as gradually to surround the whole cornea but it also often encroaches on the cornea itself, which thereby becomes opaque in the affected region. The anesthetic form of leprosy has no such characteristic or specifically leprous appearance; the affection of the fifth nerve produces anesthesia of the conjunctiva, and even of the cornea, and if the facial nerve is attacked, wholly or in part, lagophthalmos results, as well as all the consequences of the eye being unprotected from injury.

The Treatment of a Common Cold. In the experience of F. P. Atkinson the quickest relief in case of a common cold is obtained by giving 30 minims of sweet spirits of niter and the same quantity of aromatic spirits of ammonia in 1 ounce of water, repeating the dose in two and then every four hours. Three or four doses are generally sufficient to put a stop to the discharge. Should the discharge happen to be thick when first seen, then a snuff composed of 1 gr. of cocaine, 2 gr. of menthol, and 100 gr. of boric acid quickly effects a rapid cure. When the cold has run down into the trachea, as shown by a tickling of the throat whenever a long breath is taken, then a mixture of liq. ammon. acet. ʒij, sp. ether. nit. ɱx in 1 oz. of water, every four hours, rapidly gives the required relief.

A Series of Cases of Icterus Neonatorum in a Family.—J. Busfield reports the history of a family in this respect, the children, ten in number, being born while the mother was between eighteen and thirty-four. The first, a boy, had no jaundice; the second, a girl, had it, but recovered; the next four all died with it; the seventh, a girl, and the eighth, a boy, had it but recovered. These cases were given a small dose of calomel followed by large and repeated doses of castor oil and a rhubarb and soda mixture. The same treatment was without effect on the ninth child, a boy, who died on the fourth day, as did also the tenth child, a girl. All of the children were born at full term and syphilis could be excluded.

Berliner klinische Wochenschrift, January 1, 1906.

Spirochæta Pallida in the Tissues.—Buschke and Fischer have found spirochetes in the organs of two out of six syphilitic infants. The Giemsa method was found unsatisfactory in studying sections of tissue, and the authors recommend the following method of preparation. The bits of tissue are hardened in formalin and alcohol, and are then put for three days into a 1.5 per cent. solution of silver nitrate, kept at a temperature of 38° C. They are then for twenty-four hours treated at room temperature with a mixture containing pyrogallic acid 0.2 formol 0.5, distilled water 100. They are then imbedded in paraffin and the sections may be stained either with Giemsa's fluid or with toluidin blue. The organisms are more conspicuous, however, if no counter stain is employed. By using this method the authors discovered the organisms in the liver, spleen, and kidneys as well as in the cutaneous lesions. The spirochetes appear to be the most numerous in the walls of the larger and smaller blood vessels close under the endothelium.

Enterogenic Cyanosis.—Vander den Bergh and Grutterink describe six cases of cyanosis dependent on the absorption of toxic products from the intestine. These cases could be divided into two distinct types. In one set the blood gave the spectrum and chemical properties of sulphohemoglobin while in the other genuine methemoglobinemia was present. In the cases of the former class the condition was promptly relieved by a thorough course of intestinal pugation, and in the others the cyanosis would disappear after one or two days of rigid milk diet to return again when vegetables were added to the regimen. After considerable time had been spent in experimentation it was discovered that the cause of the reduction of the hemoglobin was the presence in the blood of nitrites, probably dependent on their increased production in the diseased intestinal canal.

Münchener medizinische Wochenschrift, January 2, 1906.

Thoracic Operations in the Pneumatic Cabinet.—Sauerbruch describes the operations which have so far been performed in the pneumatic cabinet designed by him for the purpose of rendering operations on the thoracic viscera possible without giving rise to danger from the pneumothorax. He first reiterates his former claims to the effect that it is preferable to use the negative pressure apparatus containing the patient's body together with the operator and his assistants, rather than to resort to the so-called positive pressure apparatus advocated by several other authors and in which distention of the lung is maintained after opening the pleural cavities by the increased atmospheric pressure in a small chamber containing the patient's head only. In practice it was found that a negative pressure of 8 mm. was most suitable for the routine adjustment of the apparatus. According to the conditions this was occasionally allowed to rise to—4 or—6 mm., and before closing the thorax was reduced to—12 mm. in order to insure close adaptation of the lung to the chest wall. Chloroform was found to have distinct advantages over either as an anesthetic. In some in-

stances a simple intercostal incision gave sufficiently free access for the performance of the necessary manipulations, but in others one or more ribs were resected. In all sixteen operations were performed; two of them on the thoracic wall, eight on the lungs; one on the heart and five on the esophagus. In connection with the first class of cases the authors point out the advantage that results from the possibility that is now given of successfully attacking mammary carcinoma even after the deeper structures are involved. In one of his cases portions of several ribs, together with the adjacent soft parts, were resected on this account and the resulting gap covered over by a large pedicled flap of skin and muscle taken from the other side of the chest. The result was excellent, the flap apparently becoming firmly fixed to the underlying lung, which was in direct contact with it. The operations on the lungs for various conditions, were also for the most part satisfactory in their outcome, but the cases of resection of the esophagus all resulted fatally. The author attributes this largely, however, to improper selection of patients and to the imperfection of the technique in dealing with this hitherto unexplored province of surgery.

Experiments on Anthropoid Apes in Regard to the Tuberculosis Question.—Von Dungern went to Sumatra in order to carry out experiments on gibbons relative to the comparative virulence of human and bovine tubercle baccili. Owing to the susceptibility of the animals to various forms of infections they are difficult to maintain in captivity even in their native country, but a sufficient number of experiments were brought to a successful termination to permit of definite conclusions. So far but little unimpeachable evidence has been secured to indicate that the bovine tubercle bacillus is less virulent for man than for cattle, and von Dungern's experiments seem to be in accord with the view that there is little if any difference in virulence between the two organisms. One set of the apes were given human bacilli subcutaneously and by the mouth, while another set were similarly infected with bovine bacilli. The infections in each case resulted fatally at about the same period, and though some differences in regional distribution were observed, the series of experiments was too small to justify the author in drawing conclusions in regard to this matter. The fact that the Perlsucht bacilli are just as virulent for apes as for cattle, whereas the former are much more closely related to man than are the latter animals, warrants the conclusion that they would be equally hostile to the human organism.

Fatigue Toxin and Antitoxin.—Weichardt continues the description of his observations on the fatigue toxin and states that he has discovered that it is possible to produce artificially a substance which apparently is the same as that formed in the bodies of experiment animals subjected to excessive muscular work. The artificial fatigue toxin can be obtained by subjecting albuminous material of various sorts to reducing or oxidizing agents. Egg albumen, placental extract, plant albumins, and pollen, all yielded substances apparently similar to that already studied. Although numerous chemical processes were found to produce active toxins the most satisfactory method for their manufacture was discovered to be by means of electrolysis. In this way fatigue antitoxin was obtained from the bodies of dead tubercle bacilli, and also from the fresh serum of a rabbit. The author concludes that the molecule of albumin when undergoing decomposition has the tendency to form as byproducts to more stable compounds certain toxic substances which belong to the class of genuine toxins. In response to the presence of these the animal body forms antibodies. The fatigue toxin is probably neither a reduction product nor an oxidization product of the albuminous molecule, but is a byproduct formed in the process of decomposition.

Deutsche medizinische Wochenschrift, January 4, 1906.

Miliary Tuberculosis.—Ribbert reiterates his former statements to the effect that the view as to the causation of miliary tuberculosis held by Weigert and his followers is erroneous. Their theory is that the dissemination of the bacilli takes place through the sudden escape into the blood stream of a large number of tubercle bacilli which are at once spread about through the various viscera. Ribbert takes the stand that the process of dissemination is a more gradual one, and believes that this must be so owing to the fact that tubercles which are manifestly of very different ages often occur side by side. In his opinion minute tubercles of the intima of the blood vessels play a prominent part in the process. By making serial sections of the lung, for example, he says that it is possible to discover them in their earliest stages as minute prominences of the arterial wall, and from these he believes a further propagation of the organisms takes place. Circulating blood does not afford a favorable culture medium for tubercle bacilli, which soon disappear from it unless the supply is constantly reinforced. According to Ribbert the original point of entrance of the bacilli into the blood does not discharge its whole cargo of germs at once but continues to permit their escape over a considerable period of time. The intima foci of the pulmonary arteries when occurring in the smallest branches promptly cause these to be occluded, and the identity of the vessel can then no longer be recognized when sections of the tissue are examined. In this way the uniform distribution of the tubercles throughout the entire lung is explained.

Local Anesthesia.—Braun in discussing this subject attributes a great deal of importance in the development of the technique to the introduction of the use of adrenalin solution. This greatly increases the efficacy and reduces the disadvantages of cocaine and its congeners. Tropacocain alone is an exception and cannot be used in combination with any of the suprarenal preparations, as it almost entirely destroys their specific action. In discussing the various fields of utility for local anesthesia the author says that both laryngology and rhinology owe their modern state of perfection almost entirely to the possibility of producing local anemia, abolition of reflexes, and insensibility to pain in this way. Esophagoscopy also has been rendered possible through the application of cocaine. In dentistry it is claimed that the introduction of the adrenalin mixtures is going to render the administration of general anesthetics unnecessary except for children or nervous individuals. Operations on the bladder and urethra while possible under local anesthesia are preferably done with the aid of medullary anesthesia. The author is not in favor of attempting to extend the field of local anesthesia into the domain of major surgery except in the case of especially suitable operations and patients, such as the radical cure of hernia in thin individuals. In any event the most precise anatomical knowledge, particularly regarding the innervation of the parts involved, and judgment in the technique of administration are essential in producing successful results in the use of local anesthesia.

The Effect of Cholin Injections on the Leucocytes.—Werner and Lichtenberg describe experiments in the course of which cholin was injected subcutaneously into rabbits and leucocyte counts made at short intervals. It was found that a prompt and often extremely marked diminution in the number of leucocytes was produced. On comparing their own results with those obtained by Helber and Linsner who examined the blood of rabbits that had been exposed to the *x*-rays, the authors found numerous points of similarity. These comprised the rapid diminution in the leucocytes, the increased tendency to hyperleucocytosis following prolonged application of the irritant, individual peculiarities in the reaction of different animals, the evidence of degenerative changes shown by the leucocytes, and the slightness of the general disturbance produced by the treatment in either case. These considerations induce the authors to suggest the advisability of making therapeutic trials with cholin in diseases that are amenable to treatment by the *x*-ray.

French and Italian Journals.

The Toxicity of Eggs.—Linossier declares that the toxic action of eggs is sometimes noted in man following the ingestion of perfectly fresh hens' eggs. The symptoms of intoxication are exclusively gastrointestinal. Very few people suffer from the symptoms due to intoxication by eggs; but when they are affected in this way the susceptibility is constant and sometimes they are sensitive to the smallest quantity. In certain cases it might be thought that autosuggestion plays a part, but the writer has been able to convince himself that the phenomena of intoxication manifest themselves when egg is introduced into the food unknown to the patient. There is a strong analogy between the toxicity of eggs and that of substances causing urticaria which is manifested in only a small number of people who have this predisposition. Brocq considers that the white of egg causes urticaria.—*La Presse Médicale,* December 6, 1905.

Extensive Lupus of the Face Cured by Radiotherapy.—Barjon reports the history of a patient who was completely cured of very extensive lupus of the face after suffering from this disease for nineteen years. The woman, 41 years old, had come to the hospital for treatment of osteitis of the foot, and during the period of surgical treatment of this lesion Barjon applied the Roentgen ray to the lupus. This affection which had at first shown itself nineteen years before, affected the entire left side of the face. It was characterized by a series of nodular and scabby foci surrounded by red inflammatory zones. The treatment

by the *x*-ray, which comprised fourteen sittings, was given within a period of about two months. Improvement was rapid. At the last nothing abnormal could be noticed on the face. This healed condition at the time of Barjon's report had lasted for more than six months. The cosmetic result was excellent. The rapidity of this recovery is remarkable especially when the extent and the age of the lesions is considered.—*Lyon Médical*, December 3, 1905.

Osteomyelitis of the Upper Extremity of the Right Femur.—Princeteau had this case under his charge. Several operations were performed during the course of the disease. The first consisted of incision followed by drainage. At the second, curettage of the femur was performed. After this intervention the albuminuria almost disappeared and a notable improvement in the general condition of the patient took place. Three or four months later there supervened facial paralysis of peripheral origin, anasarca, oliguria, uncontrollable vomiting, and a semicomatose state. At the third operation the right kidney, which seemed to be the more diseased, was exposed, and two grafts of a rabbit's kidney were made. A notable improvement followed, but death took place after some days from pulmonary congestion. At autopsy the other kidney was found to be very much diseased. A nutmeg liver was found, and the spleen was very diffluent. Princeteau felt that in spite of the termination of the case, surgical intervention had been of use.—*Journal de Médecine de Bordeaux*, December 3, 1905.

Rheumatism, Its Pathogenesis and Treatment.—Albert Robin recently presented to the French Academy an original work by Pénières bearing the above title. This writer believes that rheumatism is due to autointoxication provoked by the introduction into the blood of a toxin, a ferment analogous to the fibrin-ferment of coagulated blood studied and isolated by Schmidt. He thinks that this ferment is eliminated by the urine as it is formed, just as are other toxins contained in the normal urine. Thanks to this elimination, the organism does not suffer from the absorption of the poison. But when a lesion develops in the mucosa of the genitourinary apparatus, the rheumatic poison shows its effect on the individual because it is absorbed and enters the blood. If the epithelium of the urinary passages which serves as a defense to the organism against urinary poison is eroded, the way is opened for absorption of the poison and autointoxication follows. The writer calls attention to the fact that various affections of the genitourinary system, such as ureteritis and cystitis, are the forerunners of rheumatism. This new conception of the disease opens up fresh lines of therapy. The lost epithelium must be renewed and the elimination of the toxins must be favored. The writer makes use of mild and easily digestible antiseptics that he has discovered in the resins of cubebs and juniper. In this work are cited observations of patients with rheumatism of various types treated successfully by this new method.—*La Tribune Médicale*, November 18, 1905.

Position as a Diagnostic Sign in Angina Pectoris.—Leone Minervini regards the position of the patient suffering from an attack of angina pectoris as of much importance in diagnosing the attack from asthma and cardiac diseases of a different nature, as well as from renal disease. He gives the histories of nine cases observed by him, with photographs of the positions assumed when attacked walking, sitting, or in bed, to show that there is a uniform position assumed, which is the one dictated by nature to relieve the increased arterial pressure which accompanies the attack. The position assumed by the asthmatic is bending forward, with the elbows supported. That of the angina patient is fixed with the head and body thrown backward and the arms raised. When seized while walking the patient seeks a support against a wall, or sinks into a chair. When in bed the patient sinks his head in the pillows, with the body in extension, or slight opisthotonos. Angina pectoris is a cardiac neurosis occurring in persons with high arterial tension and in arteriorscleorosis, interstitial nephritis and aortic insufficiency. In these conditions the circulation is not influenced by gravity; hyperextension is instinctive in order to produce congestion of the bulb and the neck, and thus get vasodilation to relieve the attack. The patient thus aids the effect of the medicinal vasodilators that are administered. There is a true compensatory reaction that is instinctive to the patient. This position serves to diagnosticate between asthma produced by the respiratory system, and angina, which arises from the circulatory system. In laryngeal dyspnea the patient throws himself about.—*La Riforma Medica*, November 18 and 25, 1905.

Passage of Anti-Bodies into the Blood of Infants.—Felice la Torre experimented on 17 nurses, suckling 17 babies from one month to two years old, all healthy and in good condition. From 3,000-6,000 units of Behring's serum were injected into the women, in three injections at intervals of three days. The first blood was taken from the infant before the injections, the second, three days after the last injection. The author concludes that the passage of specific anti-bodies into the blood of the infant takes place through the means of homologous sera. Such passage takes place in very small amount: it does not vary with the age of the child: injection of ethereal sera are not devoid of bad effects on adults, because they have not the toleration of infants: owing to the small quantity of anti-bodies that pass into the system of the baby from the milk, and its slowness of passage, the gastrointestinal method of introduction has no value, either prophylactic or curative.—*Il Policlinico*, December, 1905.

Regeneration of Nerve Fibers.—Perroncito finds that the regenerative processes in several nerve fibers begin at the end of forty-eight hours after the wound, much earlier than is generally supposed. At this time there already exists a small cicatricial zone invaded by the new-formed fibers. Studying the question up to the twentieth day after the injury, the author shows that the fibers originate from the cut ones and follow the process and the method of development by which they are produced, their progress into the cicatrix and its entrance into the peripheral fragment of the nerve. He describes special formations found in the zone in which regeneration takes place, represented by terminal buttons of fibrillar nerve structure, in relation with nerve fibers and with special cellular elements. In the peripheral segment of the nerve the medullated nerve fibers do not degenerate, and terminate at the central extremity with characteristic swellings, of granular masses of unknown significance, related to certain nuclei. These formations exist until the entrance of the nerve fibrillæ from the central portion.—*La Riforma Medica*, November 25, 1905.

Antagonistic Action of Normal and Therapeutic Serum Against the Development of the Tubercle Bacilli.—F. Figari and G. Porrini, after experiments on the antagonistic action of serums against the development of the tubercle bacillus, gives us these conclusions: 1. Preventive injections of physiological serum and of horse serum are incapable of preventing the development of the tubercle bacillus when injected into the peritoneum. Injections of antitoxic serum help the localization and impede infection. Injections of goat serum from animals treated with aqueous extract of living bacilli render guinea-pigs refractory to tubercular infection. 2. Normal and physiological serum mixed with living bacilli exert no action on the development of the bacilli. Antitoxic serum emulsified with living and virulent bacilli circumscribe their action and oppose a barrier to the invasion of the bacilli. 3. *In vitro* normal serum does not inhibit the development of bacilli. Antitoxic serum does inhibit their growth.—*Annali dell' Istituto Maragliano*, August, 1905.

Bactericidal Power of the Organism.—G. Saccone tells us that there is a natural power of inherent in the human organism that destroys bacteria when they enter the body. He has made experiments on rabbits, by injections of the vegetative form of the bacillus sottilis, and also by injecting its spores into the peritoneum, pleura, blood, and under the skin, to ascertain the length of time it takes to destroy a given quantity of the culture or its spores. The author sums up his conclusions thus: 1. The spores and bacilli are more quickly destroyed when injected into the circulation; it takes a longer time for them to disappear from the peritoneum and pleura; the skin destroys them most slowly. 2. The bacilli are more quickly destroyed than the spores, the bacilli disappearing in 2 to 3 hours, the spores in 27 to 28 hours. 3. The spores are transported to some distance from the site of injection and are destroyed in the hematopoietic organs, while the bacilli are destroyed locally. 4. The bacilli and spores are destroyed extracellularly, being reduced to granules except when injected under the skin, when some are taken up by the cells. 5. The organism reacts locally by the appearance of leucocytes of the polynuclear variety; even the blood shows a hyperleucocytosis when injections have been made directly into it, and when the spores have been introduced the hematopoietic organs also show a reaction marked by hyperemia and efflux of leucocytes.—*Annali di Medicina Navale*, October, 1905.

Near the Danger Line.—In an account of the Deptford tragedy a slip is made by a contemporary. It explains that "three doctors are in attendance, but the woman is not yet dead." Not long ago a daily nearly got into a libel action by saying that a patient was "no longer in danger, though Dr. X. is still visiting him."—*London Globe.*

Book Reviews.

A Text-Book of Practical Therapeutics with especial reference to the Application of Remedial Measures to Disease to their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., B.Sc., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital; one-time Clinical Professor of Diseases of Children in the University of Pennsylvania; Laureate of the Royal Academy of Medicine in Belgium, of the Medical Society of London; Member of the Committee of Revision of the United States Pharmacopœia of 1905. Eleventh edition, enlarged, thoroughly revised and largely rewritten. Illustrated with 113 engravings and four colored plates. Philadelphia and New York: Lea Brothers & Co., 1905.

The chief new features in the eleventh edition of this well-known work are the changes and additions rendered necessary by the recent appearance of the new United States Pharmacopœia. This means that the whole book has been carefully revised, new preparations and doses have been added, and some old ones have been omitted. Among the additions we note a comparative table showing the strength of the more important pharmacopœial preparations in the preceding and in the present pharmacopœia; also a list of the changes in the strength of the official tinctures in the U.S.P. of 1905. The most valuable sections of the book are those dealing with drugs and the treatment of diseases.

The success and popularity of this work are due to its sterling merit and to the author's skill in supplying the general practitioner with just the right kind of information on the best methods of treating disease. The book pays no attention to numberless preparations that flood the market; nor does it notice every line of treatment that has been suggested. But it explains fully the recognized modes of procedure, and not only states what measures should be adopted, but also tells how and when to employ them, and when not to employ them. We have noticed only one weak spot in the book, and that is the attempt to compress the Latin of prescription writing into the brief space of a page and a half; this should be expanded or omitted.

A Compend of Histology. By Henry Erdmann Radasch, M.S., M.D., Associate in Histology and Embryology in the Jefferson Medical College; formerly Fellow in Chemistry in the University of Iowa; formerly Lecturer on Chemistry and Director of the Chemical Laboratories in the College of Physicians and Surgeons, Keokuk, Iowa, with 98 illustrations. Philadelphia: P. Blakiston's Son & Co., 1905.

This compend begins with a chapter on technique, and then takes up the histology of the cell, and the various tissues and organs of the body, and concludes with chapters on the special senses. The book is well written, accurate, sufficiently illustrated, and will serve the purpose for which it was published.

Clinical Treatises on the Pathology and Theriphy of Disorders of Metabolism and Nutrition. By Professor Dr. Carl von Noorden, Physician in chief to the City Hospital, Frankfurt a.M. Authorized American Translation. Edited by Boardman Reed, M.D., Late Professor of Diseases or the Gastrointestinal Tract, Hygiene, and Climatology, Department of Medicine, Temple College, etc. Translated by Florence Buchanan, D.Sc., and I. Walker Hall, M.D. Part VII. Diabetes Mellitus, its Pathological Chemistry and Treatment. Lectures delivered in the University and Bellevue Hospital Medical College, New York. Herter Lectureship Foundation. New York: E. B. Treat and Company, 1905.

The well-known part that Prof. von Noorden has played in bringing the knowledge of diabetes out of its formerly chaotic state into what, if not complete understanding, is now at least orderly ignorance, entitles the present volume to careful study on the part of all those interested in this mysterious disease. The reader's expectations will not be disappointed, for these 200 pages of large print contain an admirably concise exposition of what is known and what is yet to be learned concerning diabetes mellitus, expressed in simple and practical fashion so as to be of the greatest possible service to the practitioner. The first eighty pages are concerned with the problems involved in the question of the various forms of glycosuria; a discussion of the chemistry and significance of the acetone bodies occupies the next twenty pages; and the remainder of the volume is almost evenly divided between the section on the general course and prognosis of the disease and that on its treatment. The latter is perhaps the portion of the volume that will prove most interesting to the practitioner, and it embodies in little space the modern doctrine of the management of diabetics. The necessity for radical individualization in each case is insisted on, and the author's plan of determining the patient's carbohydrate tolerance is explained. Dr. von Noorden lays rather more stress on keeping the glycosuria down to a minimum than has been the custom with some writers, and he states that the appearance of a small amount of acetone or diacetic acid in the urine is not necessarily the signal for a panic-stricken return to a carbohydrate diet it is usually supposed to be. Under suitable conditions, if the rigid diet is persisted in, the acetone bodies will disappear again, and the patient will be left much better off than before. Of drugs he gives opium and the salicylates first place, and also considers the coaltar products and jumbul of use. The oatmeal cure is highly praised. A series of analytical food tables closes what is an extremely useful and practical book.

Indigestion. The Diagnosis and Treatment of the Functional Derangements of the Stomach. By George Herschell, M.D. Chicago: W. T. Reener & Co., 1905.

This is the third edition of Herschell's well-known work. It well serves the purpose of guiding the physician in the management of the functional derangements of digestion, which form a large part of his daily work. Good rules are laid down in this book for the hygiene of nutrition, and a warning is given regarding the use of alcohol, tobacco, and tea. Recipes are also given for the preparation of the different foods for the dyspeptic. The book deserves to be well recommended.

The Diagnosis of Tuberculosis of the Lung. With Special Reference to the Early Stages. By Dr. K. Turban of Davos, Translated by Egbert C. Morland, M.D., and with an Introduction by Sir Dyce Duckworth, M.D., LL.D., F.R.C.P. New York: William Wood & Company, 1905.

In placing before English readers three sections of Dr. Turban's valuable work on the diagnosis of tuberculosis, Doctor Morland has rendered no inconsiderable service to English readers. Turban's work was originally published in 1899, but the present translation has been carefully edited by the author, and pertinent annotations have been made by the translator, making the little work thoroughly up-to-date and succinct.

The first section bears entirely upon the diagnosis of early tuberculosis of the lung, and, while containing little that is actually new, brings into compact form all available data on the subject. In a forcible way it emphasizes points of diagnosis which, while probably at some time learned by every medical student, are certainly in the majority of cases forgotten. A familiarity on the part of the general practitioner with this section of Turban's work would undoubtedly make for much earlier and more exact diagnosis in tuberculosis.

The second section takes up the question of classification and nomenclature, upon which there has always been and still remains an unfortunate confusion of ideas. The schema for tabulation of individual cases suggested in this section and adopted recently by the International Conference of Tuberculosis held in Copenhagen and later by the American National Association for the Prevention and Study of Tuberculosis, is, while excellent in its way, more elaborate and consequently confusing than would be practicable for ordinary use outside of a sanatorium.

The third section is devoted to physical examination of the lung and contains many excellent suggestions, notwithstanding that the nomenclature is somewhat confusing. As remarked by Sir Dyce Duckworth in the introduction, Turban shows an evident unfamiliarity with English and American writers on the subject. Otherwise the references and the index of authors and subjects make up by no means the least valuable portion of the work.

Traité de Pathologie Interne. Par G. Lemoine, Professeur de Clinique Médicale à la Faculté de Médecine et de Pharmacie de Lille, etc. Two volumes. Paris: Vigot Frères, 1905.

The chief criticism which must be recorded against this book is the extreme scantiness with which the subject of treatment is considered. The title "Pathologie Interne" stands for what we classify under "Practice of Medicine," and the book aims to cover a field similar to that taken up by our own text-books of moderate size. Etiology, pathology, and symptoms are treated fairly completely, while diagnosis, and, as has been said, treatment, receive but slight attention. Thus the treatment of acute meningitis is dismissed in a few lines; uremia is accorded exactly ten lines; in acute articular rheumatism twenty lines are given to describe the treatment of this common affection for which so much can be done by a skilful physician. A little over half a page is devoted to the treatment of pneumonia. The book in other respects is accurate and thoroughly modern, and owing to its elementary character and its simple diction is to be recommended to American physicians who wish to become familiar with medical French.

Society Reports.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, Held in Kansas City, Mo., December 28 and 29, 1905.

(*Concluded from page 122.*)

The Effects of Osmic Acid Injections.—Dr. Joseph Rilus Eastman of Indianapolis said the injection of ten drops of osmic acid in a two-per cent. solution into sensory nerve trunks was safe. The likelihood of irritation of the kidney, however, should not be forgotten. Injections into the inferior dental or other nerves should not be made through the mouth, since infection of the wound and necrosis might result with consequent failure in the action of the acid. Immediate relief should not always be expected, notwithstanding the patients of Bennett and Murphy were all immediately relieved. No one of the writer's patients, even in those cases in which the acid was accurately injected into the nerve trunks and into the perineural fat, was promptly cured, relief coming only after one or two weeks. The observations on this point of Wright, who had a large experience with osmic injections, corresponded to those of the writer. There was very little doubt that the stretching of the nerve trunk necessarily incident to the injection was productive of good, supplementing, as it did, the action of the acid. There was no good reason why the stretching should intentionally be avoided, except perhaps for experimentation. In the case of small nerves, it would be found exceedingly difficult to inject directly into the nerve trunk, that is, the needle point would pass to the distal side of the thread-like nerve, or perhaps not enter the nerve substance at all, or, in spite of the utmost care, the fibers might be so teased apart by the needle point that the fluid would simply be spilt about the nerve. In such a case, in order to bring the acid in contact with all of the fibers, it was wise to clip the nerve so that the end might be bathed in the fluids. The effect of manipulation of the nerve, as by stretching, had not as yet been eliminated as a possible aid to the chemical action of osmic acid; therefore, a general anesthetic should be administered so that neurectasy or section of the nerve might be practised, if desired. The writer's experiments had shown no other changes in the nerve tissues as the result of injections of osmic acid than the disintegration of fat and oil globules in the perineural space and in the white matter of Schwann, such white matter of Schwann being simply fatty matter in a fluid state, insulating and protecting the essential part of the nerve. The degenerations appearing in the nerve itself were only such as might be fairly attributed to nutritional changes and exposure, the indirect result of the selective action of osmic acid in destroying fat. There was no reason why this fat should not be restored and the nerve again become capable of transmitting sensation, and the neuralgia return after injection of osmic acid. The injection of osmic acid for the relief of tic douloureux was quite justifiable even if it should become necessary to repeat the injections at intervals of a few months, particularly in view of the unfavorable results of the so-called radical operation. The solution of osmic acid should be made fresh for each operation, as deterioration was rapid.

Twentieth Century Surgical Problems.—This was the title of the President's address, which was delivered by Dr. H. D. Niles of Salt Lake City, Utah. No one who had kept in touch with our recent experiences in the surgery of the brain, lungs, pancreas, spleen, peritoneum, and other organs, he said, could escape the conviction that with a clear idea of the physiology of these parts the result of surgical endeavors would be infinitely more satisfactory than we were able to obtain with our present knowledge. In brain surgery our many failures could not be charged to any lack of operative skill, but to inability to locate accurately the exact lesion early enough to insure its safe removal or correction. The same might be said of the morbid conditions of the spleen, pancreas, and in a degree of the stomach. Until we were better informed by the physiologist of the normal functions of these organs, we could not hope always to differentiate between the normal and the abnormal. The evidence that pointed to the one and excluded the other could come to us only through concentrated specialized efforts which the average surgeon was technically unfitted to undertake. The line that divided surgical diseases from non-surgical was still somewhat vague and indistinct, and one of the most common sources of error in treatment arose from the fact that we were often in doubt as to when and how far we might safely trust to the reparative resources of nature, and under what conditions prompt operative interference should be resorted to. Thus far success in surgery had been measured largely by the ability to cope with advanced disease after it had become an immediate menace to life and health. But the time could not be far distant when the importance of recognizing the antecedent pathology of cancer, ulcer, surgical kidney, pus tubes, prostatitis, and many other grave lesions, would be impressed upon the profession, and the public would be educated to choose preventive rather than last-resort surgery. If we were ever to solve the problems that baffled our endeavors to-day, and place surgery upon a much higher plane than it now occupies, he thought scientific workers must become more practical; practical workers must become more scientific, and physicians and surgeons must become more nearly united in their ideas of pathology and treatment. All this could be accomplished only by an organized movement tending to bring all workers into closer touch and sympathy with one another.

Chylous Cysts of the Mesentery.—Dr. Miles F. Porter of Fort Wayne, Ind., said that a study of the literature together with the reports of twenty cases, including one of his own, formed the basis of the paper. The literature was very meager; the best of it was to be found in current publications. The history was bound with that of mesenteric cysts in general. Cysts of the mesentery were first classified by Portal, in 1803. Killian reported the first cyst treated surgically, but Bramann's was the first one operated. Carson was probably the first in America to report a case of chylous cyst treated surgically. These cysts were very rare, more so than were serous cysts. The origin of chyle cysts must be regarded as manifold. They might be single or multiple, unilocular or multilocular, and multiple cysts might become multilocular single cysts and later unilocular by pressure absorption. There was nothing distinctive in chylous cysts save their contents and location. An exact diagnosis was neither possible nor necessary. A centrally located movable tumor crossed by bows would be almost diagnostic of mesenteric cyst. Puncture for diagnostic purposes was condemned. Belly pain was a common symptom, and recurrent attacks of pain accompanied by vomiting and other symptoms of bowel obstruction were very significant. Chronic increasing constipation was a frequent symptom. A history of trauma was common. The treatment was surgical and the technique would depend on the findings in each case. The fear of permanent chylous fistula in cases treated by drainage was unfounded.

Treatment of General Peritonitis.—Dr. Donald Macrae, Jr., of Council Bluffs, Iowa, read a paper on this subject, in which he advocated the Fowler position in all suspected peritoneal infections; also the institution of free drainage at the time of the operation by means of large-sized rubber tubing only. Drainage of the most dependent part of the pelvic peritoneal pocket was imperative. He urged the removal of the primary pathological factors when possible, and spoke against the use of gauze and flushing. He said the drainage tubes should be aspirated at frequent intervals.

Appendicitis.—Dr. I. B. Perkins of Denver read a paper in which he gave further reports from physicians who had suffered from this disease. He discussed the diagnosis of chronic appendicitis and the prodromal stage in acute cases.

He expressed himself in favor of early operation in all cases. The interval cases should be operated upon. Fatalities were usually chargeable to delay. The management of delayed cases was discussed; also the attitude of the profession and of the public toward operation.

Treatment of Appendicitis.—Dr. O. Beverly Campbell of St. Joseph, Mo., followed with a paper on this subject, in which he drew the following conclusions: (1) In incipient appendicitis, until the patient was placed in the hands of the surgeon, all food and drink should be withheld, and the patient nourished per rectum. (2) Every patient should be advised of the advantages of an early operation. (3) Radical work, that is, the removal of the appendix, or the closure of an opening in the cecum, should be made, in abscess cases, when it could be done without additional risk to the life of the patient. (4) The practice of merely draining in every abscess case should be condemned as non-surgical. (5) Operation during a progressive diffuse peritonitis was attended with a higher mortality than the method of procedure recommended by the writer. (6) If the internist would direct his efforts in the treatment of appendicitis toward the protection of the peritoneum until he could transfer his case to the surgeon, the mortality in this disease would be greatly lessened. (7) The adoption of the more rational method of dealing with diffuse peritonitis would convert a large percentage of these cases into circumscribed peritonitis, when they could be rightly classed as large abscess cases, having the same mortality.

Treatment of Appendicitis in its Various Stages as it Comes to the Surgeon.—Dr. C. H. Wallace of St. Joseph, Mo., contributed a paper with this title, and summarized by saying that (1) appendicitis was always a surgical disease; (2) every patient should have and was entitled to operative relief within the first forty-eight hours; (3) the rapidly progressing stage was the stage of applicability of the Ochsner treatment, which was attended by the lowest mortality; (4) cases coming to the surgeon with evidence of gradually subsiding symptoms should be deferred for a more favorable operative period; (5) every interval or chronic case should be urged to the operating table; (6) abscess cases should be given two safe rather than one hazardous operation; (7) in cases of diffuse peritonitis all dependent cavaties in which there was accumulation of fluid should be carefully incised and drained, but not flushed, and secondarily the offending organ should be incised.

Dr. Van Buren Knott of Sioux City, Iowa, followed with a paper in which he set forth his ideas at length concerning the management of appendicitis, his conclusion being based upon one thousand operations.

Extrauterine Pregnancy.—Dr. J. W. Andrews of Mankato, Minn., read a paper on this subject, in which he reported having operated upon a woman who was ten weeks pregnant; the sac ruptured, and the operation was delayed thirty-six hours. The case was reported in detail. The steps of the operation he performed were not very different from those of an ordinary laparotomy. He counseled accuracy and rapidity in operating in these cases, and emphasized the necessity in many cases of thrusting the hand down through the pool of blood and securing the blood-vessels before attempting to mop out or otherwise remove the blood and blood clots. He thought drainage, as a rule, should be employed after laparotomy for extrauterine pregnancy.

Post-climacteric Hemorrhages; their Cause and Treatment.—Dr. A. L. Wright of Carroll, Iowa, called attention to the frequency of occurrence of hemorrhage after the establishment of the menopause. He spoke of how often it was passed over slightingly, with the thought that it was incident to the woman's age until grave complications were at hand, or the true cause—carcinoma in most instances—was so far advanced as to place the patient beyond the pale of surgical interference. He called attention to the several changes that take place in the uterus at this time, and cause hemorrhage. The trend of the argument was to recognize early the pathological changes taking place in the uterus, and if in doubt to remove the organ rather than take chances that would invariably result in death.

Gunshot Injuries of the Stomach.—Dr. J. N. Warren of Sioux City, Iowa, gave the history and analysis of 144 cases of gunshot injury of the stomach. He spoke of the character and location of the lesion in uncomplicated cases in determining the prognosis. In operative cases the time elapsing from the time of injury and the operation showed that the earlier the operation was performed, the more favorable was the result. In complicated cases the number of lesions found and viscera injured added to the gravity of the case. He spoke of the results in the cases that were not operated upon. He said the presence of food in the stomach with the discharge of the same into the abdominal cavity added to the danger of general peritonitis, either with or without operation.

The Symptoms of Spinal Disease.—Dr. S. C. Baldwin of Salt Lake City called attention particularly to the early symptoms of spinal disease in order that suffering might be earlier relieved and deformity avoided. The general or more common symptoms, and then such symptoms as rigidity, gait, pain, paralysis, abscess, etc., were considered. The symptoms differed when different regions of the spine were involved. For instance in the cervical region the first symptom noticed might be pain in the head, and, according to Whitman, earache might be a symptom of cervical disease. Before there was any sign of deformity the patient might complain of difficulty in swallowing and even in breathing. In the cervical region there might be and often was grunting respiration. Such general symptoms as weakness, loss of appetite, loss of weight, rigidity, and general change of gait in walking, were apparent in disease of all parts of the spine. The writer had seen a number of case of Pott's disease developing in patients over forty years of age, and two cases which he recalled occurred after the age of fifty. Weakness might show itself in a general drooping of the trunk, an unsteady and stumbling gait, and exhaustion requiring rest after the slightest exertion.

Drainage of the Male Pelvis.—Dr. William Jepson of Sioux City, Iowa, read a paper on this subject, in which he pointed out the indications for drainage of the male pelvis, and spoke of the obstacles in the way of instituting such drainage as compared with the female pelvis. He described a method of instituting drainage of the male pelvis, and reported the results he obtained in nineteen cases. In all of these cases there existed a diffuse pelvic peritonitis, with accumulations of purulent fluid often elevating the distended bowel high into the abdomen, and in two cases ascending between the mesentery and descending colon and overflowing from the pelvis into the left subrenal fossa, which was also opened and drained. In all but five cases free pus existed in the space to the outer side of the ascending colon, which in each instance was drained through the ileocostal space. In one case the distention of the paretic bowel necessitated opening and the establishment of an artificial anus. Three of the patients thus treated had died, one after an illness of nearly five months, during which time death on three or four occasions was threatened by intestinal obstruction, while a number of abscesses followed in the abdominal wall. Death resulted from exhaustion incident to the prolonged suppuration. In the second fatal case death took place ten days after the operation, due to toxemia.

Gastric Dyspepsias Amenable to Surgical Treatment.—Dr. William E. Ground of Superior, Wis., said it was now recognized that many forms of digestive disturbance were dependent upon conditions entirely outside the stomach, and involved this organ either by direct extension of the pathological process, or indirectly by nerve influence. Among these might be mentioned inflammatory or irritative conditions in the biliary apparatus, pancreas, duodenum, or appendix, and adhesions of the stomach to the surrounding viscera. Within the stomach conditions remediable by

surgical means were perforative and non-perforative gastric ulcer, chronic gastric ulcer, hemorrhage, pyloric obstruction, gastric dilatation with stasis, hyperchlorhydria, and cancer. The question of operative interference in some of these conditions was still in dispute, but the wisdom of referring cases of perforating gastric ulcer with or without adhesions, cicatricial stenosis of the pylorus, adhesions of the stomach to any of the surrounding structures, and perhaps chronic gastric ulcer to the surgeon was now pretty firmly settled. Closely associated with ulcer was the sequence of cicatrization and contraction, and when this process involved the pylorus, it led to stenosis and obstruction, and later, if this were prolonged, gastric dilatation and atony would result. Whether the pylorus was obstructed by spasm due to the presence of the ulcer or to hyperchlorhydria, which almost always accompanied non-malignant ulcer, or by the cicatricial contraction following the healing of an ulcer, the pylorus was rendered incapable of readily transmitting its contents, the stomach became distended, and its muscular walls weakened, leading ultimately to permanent atonia gastrica. Stomach dilatation might be due to atony alone, but it was much more frequently due to mechanical obstruction at the pylorus. In this condition of gastric stasis, food might remain in the stomach a day or more, whereas, as Riegel said, it should empty itself within seven hours at the most. In fairly advanced cases, when the obstruction had given rise to a compensatory hypertrophy of the stomach, the peristaltic movements might be seen and felt through the abdominal walls, usually accompanied by pain and vomiting. Later, when the stomach began to dilate and assumed a more passive state, the patient complained of fullness and epigastric pains after meals. Fermentation took place, causing eructations and heartburn, and frequently vomiting. Vomiting was a most prominent symptom when gastrectasia and fermentation were well-established. When this sequence of events was set up, there was but one remedy, and that was surgical intervention. The curative effects of operation could not be attributed to drainage of the stomach alone or to short circuiting of the food current, as was so often contended, for unless the pylorus was closed food would pass through it. The explanation the writer had arrived at was to the effect that the cutting of the circular fibers in the pyloric end of the stomach did away, to a considerable extent with the muscular unrest accompanying gastric digestion, especially when ulceration was present. To the author's way of thinking, a gastroenterostomy acted much the same as cutting the fibers of the sphincter in anal fissure. In this latter condition the feces continued to pass over the ulcer, but the paralyzed sphincter prevented friction, and it healed readily.

Restoration of the Perineum.—Dr. Howard Hill of Kansas City, Mo., said that the perineum was divided into three layers: A superficial sphincter layer; a middle ligamentous layer; and a deep layer consisting of the levator ani muscle and its fascia. An ideal operation consisted in restoring the different planes of tissue to their normal position. It mattered little which incision was used to expose the structures mentioned, but he had used a transverse incision which consisted in raising a flap of the posterior vaginal wall and had done the operation by using three layers of sutures. The first included the levator ani and its fascia, reattaching that portion of the muscle which helped to form the perineal center in front of the rectum. Next he identified and sutured the triangular ligament and attached the sphincter ani to the perineal center. A single suture was used for the bulbocavernosus.

Gluteal Cavernous Angioma.—Dr. J. E. Summers, Jr., of Omaha reported this case and said that cavernous angiomata of voluntary muscles were comparatively rare, and in the case of this report the size of the growth was exceptional. It was excised while the circulation was controlled by direct digital pressure of the common iliac artery through an abdominal incision.

Preoperative Thrombi in the Region of the Field of Operation as a Cause of Postoperative Complications and Death.—Dr. A. W. Abbott of Minneapolis said that thrombosis, especially of the veins, was often to be found, if looked for, in the vicinity of the field of operation. It might result from the pressure of a tumor, from cancer or tuberculosis, etc., or might be the result of adjacent inflammation of traumatism. Usually no attention was paid to the condition. Thrombosis in the field of operation increased the danger. Were there any practical methods for avoiding these dangers? The author believed that many cases of fatal sepsis, pulmonary embolism, and particularly many cases of so-called ether pneumonia that were otherwise inexplicable could be rightly ascribed to the infection of a clotted vein or its disturbance by rough handling, or both; so also pyemia, abscess of the liver, osteomyelitis, and other evidences of metastatic infection. Aural surgeons had formulated a definite operation for thrombi of the lateral and sigmoid sinuses, namely, ligation of the internal jugular vein and clearance and drainage of the sinus. This was an eminently successful operation considering the desperate condition which called for the interference, and, so far as the speaker knew, was the only established operation for thrombosis complicating operation. He thought a similar course should be pursued in all operations complicated by thrombosis.

Conservatism in Postoperative Treatment.—Dr. S. C. Beede of David City, Neb., referred to the increasing tendency among surgeons to hasten their patients out of bed and hospital after grave operations. His attention was first directed to this matter when members of the laity began to mention frequently the shortness of time patients were detained by this or that surgeon. Nurses would speak with pride of the fact that their favorite operator would send a hernia or an appendix case home in two weeks. Then another one, not to be outdone, made it twelve days instead of fourteen. Another, to make a better showing than his competitor, shortened the period of disability to ten days, only to be met by a more daring rival with an eight day period for a clean abdominal section. This was not the limit of extravagance in this strife to make it appear easy to be operated upon, but patients after extensive abdominal work had been carried out of bed and placed in a chair on the third day, and allowed to walk about the room on the fourth. It was creditable that the many weeks in bed once necessary could now be avoided by a more perfect technique, especially in the matters of more perfect control of hemorrhage, aseptic precautions, discarding irritating antiseptics, avoiding unnecessary traumatism, and care in suturing and suture tension. These gave the best possible opportunities for nature to do her reparative work, but nature would work only so fast, and he thought there was a limit in time beyond which it was unsafe to urge her. His contention was that this limit had been overstepped, and that the perfect result which should be the aim in every case was thereby marred.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. Malcolm L. Harris of Chicago; *Vice-Presidents,* Drs. A. L. Wright of Carroll, Iowa, and C. Lester Hall of Kansas City, Mo.; *Secretary-Treasurer,* Dr. Arthur T. Mann of Minneapolis.

Salt Lake City was selected as the place for holding the next annual meeting.

For the Control of Nasal Hemorrhage tampons can be readily prepared as follows: A layer of cotton is wound around a penholder or similar object until the desired thickness is obtained and then withdrawn. The cotton cylinder is then moistened, squeezed dry and inserted into the nasal cavity. If the projecting end of the tampon is now moistened it will swell up and thus produce sufficient compression.—*International Journal of Surgery.*

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, December 5, 1905.

THE PRESIDENT, DR. JOSEPH FRAENKEL, IN THE CHAIR.

A Case of Blindness, with Astereognosis.—Dr. J. F. TERRIBERRY presented a patient, a man, 55 years old, native of Canada, married, and of intellectual pursuits. His father met a violent death at the age of 30; his mother died at 70 of "dropsy." The patient stated that he came from a healthy stock, with no hereditary entailments. He was strong and vigorous in his early life, and continued to enjoy good health up to the time of his present trouble. For a period of about twelve years, after the age of 40, he used alcoholics freely but not steadily, and was exposed to venereal disease. He admitted having had gonorrhea and a soft chancre, but denied syphilis. He denied having been injured, and gave no history of malaria or rheumatism. He was greatly disturbed by business misfortunes and reverses for some years prior to his present illness. Between three and four years ago, while his general health was apparently good, he became aware of a slight indistinctness or blurring of his vision, both eyes, seemingly, being equally affected. His vision slowly but steadily failed for a year and a half to two years, when it was reduced to its present condition of light form perception only. This failure of sight had been unaccompanied by symptoms of any kind until about one year ago; he had had no headache, no dizziness, nausea, or vomiting, no phenomena of irritation of the visual tracts. About a year ago his wife noticed some awkwardness in his movements while dressing, and this had gradually become more marked, particularly on the left side. Upon examination, the patient presented a good general appearance. He was well nourished, and his complexion was good. His face had the blank expression of a sightless person. The left shoulder dropped a little. The left hand, in repose, gave an expression of weakness quite evident when contrasted with the right. He was able to stand and walk well. There was no tremor of the hands, tongue, or facial muscles. The left knee-jerk was normal; the right was present, but less active. The Achilles jerks were obtained, but their action was slight. Stroking the soles of the feet caused slight flexion of all the toes excepting the great toe, which remained motionless. No Babinsky sign. The tendon reflexes of the upper extremities were normal. A chain reflex was obtained. Tapping the branches of the facial nerve elicited no response. The pupils were regularly and equally dilated to double normal size. Light reflex was present, but reduced, and attempts at psychic accommodation by imagining that he was looking at near and remote objects caused no action in the pupils. The senses of smell and taste were apparently normal, a watch was heard at the normal distance. The patient was now handed a dynamometer and requested to grip it with all his strength, when it at once became apparent from the awkwardness with which he handled the instrument that there was some difficulty with the stereognostic perception. Placing the instrument properly in his grasp, he recorded with the right hand, 18, 32, and 25; with the left hand, 25, 25, and 22. The patient was requested to raise his arms above his head: this he did hesitatingly, raising the left arm part way only. He was asked to execute a number of arm movements, and was found utterly unable to do so. A number of different objects were placed in his hands, none of which he could name properly. His arms were placed in various positions, and he was unable to say what the positions were. In all of these movements, the left side was less competent if possible than the right. When asked to stand on the right foot, he stood on the left, and *vice versa*, or, apparently guessed at it. The muscle sense in the arms was absent and was very poor in the legs below the knees. When asked to cross his legs, he did so poorly. The sense of touch was good in the upper and lower extremities, and the same was true of pain and temperature perceptions. There was, however, som delay in recording these impressions. The localizing sense was *nil*. There was no ataxia of the upper or lower extremities. The bladder and rectal functions were normal. There was no change in his disposition. Attempts at determining the condition of the visual memories were not conclusive, but were suggestive of partial failure. When asked if he recalled the appearance of his friends, he replied that he could recall the sound of their voices much better than their appearance, and he believed that his memory for things seen was not good. The ophthalmoscope revealed a normal looking fundus. The urine was normal; the blood examination was negative.

Dr. DAVID WEBSTER who had made repeated examinations of the eyes of the patient said there was nothing in the appearance of the optic nerves that would account for the loss of vision. The patient still had some vision, and it was apparently growing no worse. He was unable to count fingers, but distinguished objects that were placed before his face, and was able to exercise regularly in the corridor of the hospital without coming in contact with objects. The astereognosis, which was first noticed by Dr. Terriberry, was a very interesting symptom. Any piece of paper that was placed in the patient's hand he would simply recognize as money. His symptoms pointed to a cortical degeneration, which had perhaps invaded the visual centers. The case might be put down as one of visual astereognosis.

Dr. WILLIAM M. LESZYNSKY said he had had the opportunity of examining the patient shown by Dr. Terriberry, and could corroborate all that had been said in regard to the symptoms. An interesting question to decide was whether the man's blindness was due to a lesion of the optic centers or to one anterior to the corpora quadrigemina. This could not be satisfactorily determined from a study of the reaction of the pupils, as atropine had been instiled daily. The speaker said he was inclined to the diagnosis of diffuse cortical degeneration involving the parietal and occipital areas, this being secondary to arterial changes.

Dr. TERRIBERRY in closing, said the duration of the man's illness was about four years, during which time there was a gradually increasing loss of sight. No other symptoms were noticed until a year ago. While the diagnosis was somewhat in doubt, the case was probably one of cortical degeneration. The etiological factor for this had not been made out. The man had used alcohol, but not to excess; he had never been injured; he denies having had syphilis. The change apparently began in the occipital region and extended forward toward the motor area, a little farther on the right side than on the left.

Osteoma of the Spine in the Cauda Equina Region.—Drs. MAX MAILHOUSE and WILLIAM F. VERDI of New Haven, Conn., reported the case of a man, 44 years old, a widower. His family history was unimportant. He denied all venereal disease, and had two healthy, grown-up children. For one year prior to the onset of his symptoms he had smoked and drank to excess. Early in the summer of 1905, he had first noted increased sexual desire, at times going to the extent of four or five sexual acts daily. He consulted Dr. Verdi on account of pain in the hypogastric region coming on in paroxysms, increasing in severity and frequency. Subsequently he had severe pain radiating from the suprapubic region to the back, at about the second lumbar vertebra, a little to the left. Later on the pain extended to the upper testicles and the upper and inner part of the thighs. In addition to his spinal symptoms, the patient had noticed in August that his eyes began to ache, and early in October he observed that the vision in his left eye was failing. On October 17 he consulted Dr. A. N. Alling, who found a retrobulbar neuritis, as evidenced by a central scotoma, the disk appearing normal. When Dr. Mailhouse first saw the patient, on

November 1, 1905, he obtained the same history as did Dr. Verdi. There was no spinal tenderness, and nothing visible on the back. There was no anesthesia nor analgesia on the trunk, legs, buttocks, genitals, or perineum; no paralysis; no contractures. The patient was able to stand on either leg. The knee-jerks were active, but there was no ankle-clonus nor Babinsky sign. The plantar reflexes were extremely lively, and the tactile sense very acute. Kernig's sign was marked. The general musculature was flabby, but there was no localized atrophy; no special idio-muscular contractility. No vesical symptoms were present. On November 12, there was observed some weakness of the left internal rectus, as evidenced by a deviation of the left eye.

A diagnosis was made of a tumor pressing upon the cauda equina at the level of the second lumbar spine, and, owing to the prominent irritative phenomena and the absence of motor involvement, and to the simultaneous involvement of the second and third cranial nerves, it was supposed to be a gumma. Operation was performed on November 21, by Dr. Verdi, assisted by Drs. Wm. H. Carmalt and L. W. Bacon, Jr. The spines and laminæ of the first and second lumbar vertebræ were removed, and nothing but a tense dura found. On removing the spine and upper edges of the third vertebra, however, the dura was seen to be pushed forward and compressed against the body of the bone at an acute angle, and the finger could feel a bony growth occluding the canal. The remainder of the laminæ and the tumor were then removed with the biting forceps, as the condition of the patient did not warrant a prolongation of the operation, such as the use of the saw and the removal of the tumor *en masse* would necessitate. It was estimated that the anteroposterior measurement of the tumor was about five-eighths of an inch, and its vertical measurement half an inch. Two weeks had now elapsed since the operation. The wound had healed and the patient was able to sit up and was entirely free from pain excepting that referable to the wound. The eye symptoms were reported to have progressed to the degree of some ptosis, indicating greater involvement of the third nerve. The nature of the ocular affection had not yet been determined. It apparently had no connection with the spinal lesion.

Dr. FRAENKEL said these cases of osteoma of the spine were of very rare occurrence. He recalled a case seen seven or eight years ago in which there were evidences of a progressive intraspinal lesion, which were explained at the autopsy by an osteoma of the processus odontoides atlantis.

Retropharyngeal Carcinoma, with Metastases.—Dr. B. SACHS reported this case, and showed the specimen. The patient was a man, 35 years old, who was admitted to the Mt. Sinai Hospital last summer while Dr. Hirsch was on duty. The symptoms indicated increasing intracranial pressure, with more or less somnolence, slight hemiplegia, right-sided oculomotor palsy, and a double optic neuritis. There was a large retropharyngeal mass, which was regarded as the source of his trouble, and was supposed to have perforated the base of the skull. The patient's symptoms gradually became more aggravated, headaches were intense, and multiple tumors developed in the scalp and various parts of the body. The retropharyngeal growth was rather soft to the touch, and was at first supposed to be a gumma. A section of the growth was submitted to Dr. E. Libman, of the Pathological Department of the Hospital, who, upon examination, found it to be a carcinoma. The case resulted fatally, and the skull of the patient, which was exhibited by Dr. Sachs, showed multiple perforations, indicating the sites of the metastatic cancerous growths.

A Case of Brain Tumor.—Dr. WILLIAM M. LESZYNSKY reported the case of a man, 28 years old, single, born in Russia, a photographer. He was admitted to the Lebanon Hospital on October 28, 1903, with the following history: When he was four years old he was struck on the forehead by a stone, which resulted in momentary loss of consciousness, but no further trouble followed. After this, he was always very nervous. At the age of 13 he was frightened at the sight of the killing of a mad dog, and at once became hysterical and had convulsive fits several times daily for about three weeks. Soon after his hands and feet began to shake almost constantly, and he would often fall asleep while standing, walking, or eating. He recovered from this condition at the end of two years, and came to this country at the age of 15. Since then he had often complained of heaviness in his head, and when once asleep it was very difficult to arouse him. About nine months ago he began to suffer from frequent attacks of severe general headache, preceded or accompanied by vomiting, and this had continued. About two months ago vision began to fail, and blindness soon supervened. He now complained of headache, vertigo, and general weakness, with a sensation of falling toward the right side. On admission he was unable to stand or walk without assistance. His pulse was 84, regular; temperature and respiration, normal; heart, lungs, and abdominal viscera were normal. There was no tenderness on percussion over the skull; no rigidity of the neck muscles; both pupils were equally dilated and immovable; no perception of light in either eye; ocular motility normal; bilateral papillitis of six diopters, with numerous retinal hemorrhages; smell and hearing normal; slight left facial paresis of the lower branches; the grasp was weaker on the left side, and there was slight uncertainty in distinguishing objects with the left hand. Muscular power and resistance was otherwise good in all extremities. Both knee-jerks were equally active; no clonus; the plantar, Achilles, cremasteric, and abdominal reflexes were normal. No objective sensory disturbance. Urine and blood examinations negative. The patient was delirious at times, and had occasional attacks of headache and vomiting. These symptoms were relieved by cathartics and suitable diet. He gradually became worse, and for a time the symptoms increased in intensity, and there was paralysis of the right external rectus, with irregular astereognosis, slight ataxia, and exaggerated reflexes. He was kept in bed, and, in addition to general management, iodide of potassium was administered in increasing doses, and rapid improvement in all symptoms soon followed. In February, 1904, with the exception of the blindness and beginning optic atrophy, he was apparently in perfect health and able to walk about the wards and corridors without assistance other than the guidance required by a blind man in order to avoid accidents. He was then taken to an institution for the blind, where he remained until readmitted to the Lebanon Hospital on September 23, 1904. At this time his bodily condition and general health were good. Careful and frequent examinations failed to reveal any evidence of disease of the nervous symptom, other than commencing postneuritic optic atrophy. During his three months' sojourn in the hospital, he occasionally complained of headache and vertigo. He was discharged January 1, 1905, and remained at home about six weeks, when he was again placed in an institution for the blind for about six weeks, where he became so ill that he was removed to the house of a relative. While there he had frequent attacks of severe and uncontrollable headache, with vomiting, delirium, and general convulsions, with loss of consciousness, varying in frequency from one attack every twenty-four hours to one every two hours. During the intervals he was always rational. This condition continuing for several weeks, he was removed to the Kings County Hospital, May 15, 1905. He was admitted to the service of Dr. A. C. Brush, who noted, in addition to the blindness and papillitis, "memory poor, attention and volition slow; complained of headache, and had occasional outbursts of delirium; examination otherwise negative in result. The diagnosis of cerebral tumor was made, but the growth was not localized. He remained in the same condition for ten days, and was found dead May 25, 1905." The autopsy was performed by Dr. B. Joseph, resident

pathologist, to whom the speaker was indebted for the specimen and the following notes: "Skull somewhat enlarged. Calvarium normal. Numerous erosions of the internal surface of the right side of skull. Right hemisphere about one-third larger than the left and intimately adherent to the dura. Pia mater on the right side altogether obliterated; on left side edematous. Cerebral cortex on right side thinned. Ventricular cavities contained about eight ounces of clear serous fluid. Attached to the right internal surface of the right lateral ventricle was a tumor about the size of a hen's egg, of cauliflower-like appearance, and exhibiting discrete areas of darker and lighter colors. Upon section, the tumor gave a grating sensation to the knife. The posterior fornix of the right ventricle was enlarged to about twice its normal size. The tumor, upon microscopic examination, proved to be a small, round-cell sarcoma, containing areas of calcareous deposits." This is the second case of brain tumor occupying the lateral ventricle that had come under the speaker's observation. On account of the marked and rapid improvement following the use of potassium iodide, it was thought for a time that a mistake had been made, and that the case was one of syphilitic basilar meningitis, but the autopsy proved otherwise.

Dr. Arthur C. Brush of Brooklyn, who had seen the case reported by Dr. Leszynsky, said that while the patient was under his care he had shown symptoms of a brain tumor, but at that time it would have been difficult to localize it. No history was obtainable from the patient. He was dull and apathetic, and the answers he made to questions were not to be relied upon.

Familial Multiple Sclerosis.—Dr. I. Abrahamson showed two out of three brothers who were affected with this disease. The three patients, Edward M., aged 19 years, Louis M., aged 16 years, and John M., aged 15 years, were all born in the United States, of Bohemian parentage. Both parents and two younger children were alive and well. Two children, unaffected with this disease, had died in infancy. There was no history of miscarriages. The father positively denied lues; his sister was epileptic; the mother's brother was insane. Otherwise the family history was negative.

Etiology, Prognosis, and Treatment of General Paresis.—Dr. Joseph Collins read this paper. (See page 125.)

Dr. M. Allen Starr said that from his own experience he could corroborate much that Dr. Collins had said in regard to the etiology of general paresis. A year ago Dr. Edward L. Hunt, one of his assistants at the Vanderbilt Clinic, went over the statistics of the Clinic for the past seven years and analyzed the cases of general paresis that had come under observation there. The result of his investigations corroborated, to a large extent, the statement made by Dr. Collins, and the same was true of an analysis of one hundred consecutive cases seen by Dr. Starr during the earlier years of his practice. Of those one hundred cases the histories were practically complete, the patients having died. The statistics, both from his personal and dispensary cases, agreed very closely. Over 59 per cent. were clearly, unquestionably syphilitic. Of the cases he had seen in private practice, 64 per cent. were undoubtedly syphilitic. The speaker said that he differed with the statement of certain French and German writers that all cases of general paresis and tabes were syphilitic; on the contrary, he believed that in many instances both of these affections were distinctly non-syphilitic. Many, as Dr. Collins had said, were due to trauma, and many were due to alcoholism, and a certain number could not be accounted for on any of these grounds, but were due to the wearing out of the brain tissue in connection with the stress and strain incident to the worry of an active, energetic life. Dr. Starr said that an analysis of a large number of cases of general paresis had convinced him that the early symptoms of the disease did not correspond very closely with the statements in the textbooks. In only 20 per cent. of the cases he had observed were there any mental symptoms at the outset, leaving about 80 per cent, in which the physical symptoms appeared before the mental phenomena. In the latter cases there was no exaltation; no failure of memory at the beginning. The speaker emphasized, as Dr. Collins had done, the importance of a careful physical examination in every case of so-called neurasthenia, because the early symptoms of general paresis manifested themselves in ways that would tempt one to make the diagnosis of neurasthenia if one contented himself with a superficial examination. The presence of the Argyll-Robertson pupil, a tremor of the face and tongue, marked exaggeration of the knee-jerks or their persistent absence, were significant early symptoms of general paresis. Another symptom which the speaker had found of considerable importance was what he called the reaction time of the patient. This was measured by means of the Galton instrument, which consisted of a pendulum swinging backward and forward in exactly one second. The pendulum could be immediately started and arrested by the pressure of a finger on a key. The patient sat with his finger on this key, and was instructed to press the key simultaneously with the exhibition of a light or color, or upon the striking of a bell. By this method it was a very simple matter to determine the reaction time of the patient. Dr. Starr said he had resorted to this test in many cases of neurasthenia and general paresis, and he had found that in the former condition the perception was very keen at the beginning, but gradually decreased after repeated tests, while in general paresis the perception was below the normal from the very start, and the time reaction lengthened as the disease progressed. He thought this test was of some value in differentiating between general paresis and neurasthenia. The differential diagnosis was of great importance because of the question of prognosis and treatment. It was well known that there were cases that presented all the symptoms of general paresis that were actually cases of cerebral syphilis. He recalled such a case where, after a diagnosis of general paresis, the patient recovered under antisyphilitic treatment, and was now in good health after fourteen years had elapsed. About 15 per cent. of the cases of general paresis began with the symptoms of hemiplegia; about 20 per cent. with the symptoms of neurasthenia and sleeplessness, and about 20 per cent. with some signs of exaltation. This behooved the neurologist to be very careful in his diagnosis, and in every instance the patient should be given the benefit of the doubt and put upon specific treatment.

Dr. B. Sachs said that the difficulties of the subject were largely due to the fact that although the greatest effort had been made during the past fifteen years to establish an accurate clinical picture of general paresis, the more closely the disease was studied the more we became impressed with the idea that the term, general paresis, unquestionably included a number of very divergent clinical pictures, and for that reason any statistics that were collected would naturally differ and be somewhat misleading. The speaker said he was in entire agreement with Dr. Starr that there were certain cases of cerebral syphilis or pseudoparesis which could not, at certain stages, be differentiated from genuine dementia paralytica. In discussing the question of dementia paralytica occurring late in life, Dr. Sachs said that of 283 cases seen at Bellevue in the year 1904 at least 14 per cent. occurred after the age of fifty; 4 per cent. after fifty-five, while only 0.7 per cent. occurred after the age of sixty; 72 per cent. occurred between the ages of thirty and fifty. In regard to the interval between the original syphilitic infection and the development of the first symptom of general paresis, Dr. Sachs said he could recall at least two cases in which the mental disorder was recognized within less than one year after the initial infection, and the subsequent course of events verified the diagnosis. He had seen a number of other cases in which the general paresis developed within three years after the chancre. As to the curability of the disease, the speaker had written an article some years ago in which he was very hopeful of the prognosis, especially

if the condition was recognized early. That paper was written some eight years ago, but he was now prepared to make one statement very positively. After an experience of over twenty years, during which he had observed several hundreds of cases of general paresis, he could not recall a single instance in which the patient had survived over eight years. When the diagnosis of general paresis was honestly and carefully made, the claim could not be established that the disease was curable. In spite of that fact it would be a great mistake to abandon efforts at treatment, and simply pronounce every case incurable. Mistakes in diagnosis were not infrequent, and with that possibility in mind the patient should always be given the benefit of the doubt and receive a thorough course of antisyphilitic treatment, particularly if the case was seen early. While he was far less hopeful in regard to the curability of the disease than he was eight or ten years ago, he still believed that justice to the patient demanded that antisyphilitic treatment should be given a trial. So far as the etiology of the disease was concerned, Dr. Sachs said he believed there was at least one other important etiological factor besides syphilis, and that was trauma. The same was true in reference to tabes. Syphilis, of course, was the most important factor.

Dr. Adolf Meyer said we should always be prepared to acknowledge that a diagnosis of general paresis could not be said to be absolutely certain in more than about 90 per cent. of the cases that came under observation under that name. There was a margin of about 10 per cent. where we had to depend upon the autopsy and anatomical findings, and then the question arose, what anatomical findings should we consider as being conclusive evidence of general paresis, a question which should be discussed to put the entire problem of the etiology and therapeutics of general paralysis on a safe basis. There were, of course, cases in which alcoholism was the only ascertainable etiological factor, while other cases appeared to be due to trauma. We should, however, remember how very difficult it was to absolutely exclude syphilis in a case of general paresis, and while it was not necessary nor even justifiable to proclaim, *pro publico*, that every case of tabes and general paresis must be of syphilitic origin, we could give our statistical facts as evidence in favor of our conviction, and we should with equal sincerity admit that we had no means to exclude previous syphilis positively in any case. The speaker suggested that when Dr. Starr claimed that in only 20 per cent. of his cases were early mental symptoms noted, he must have had in mind the so-called legal insanity. If we took legal insanity as a standard in psychiatry we would have a poor task in psychiatric diagnosis. As a matter of fact, we had to depend on much more subtle evidence, and we would consider above all things the nonconcern over blunders by the patient which made even slight memory defects appear as an ominous feature. These, and many changes of character and judgment need by no means reach the standards of legal insanity to become decisive factors in the diagnosis, and were certainly much more conclusive than changes of reaction time. A great difficulty was connected with our ignorance of the bearing of many relatively insignificant disorders that sometimes appeared after syphilis, such, for example, as an Argyll-Robertson pupil. He referred to cases with previous syphilis, and perhaps with one Argyll-Robertson pupil, in whom recurrent attacks of manic excitement were very difficult to interpret. With regard to the administration of antisyphilitic remedies, Dr. Meyer said we should realize that it meant hardly more than a desire to spare the patient the consequences of a possibility of error of diagnosis. It had really no other logical foundation, inasmuch as there was hardly any reason to fear that a case of cerebrospinal syphilis would become one of general paralysis on account of delay of such treatment. Probably nothing would be lost in any case if we should wait until the diagnosis became more obvious. Under all circumstances, the "result" of such treatment would be a treacherous guide in the diagnosis.

Dr. R. A. Diefendorf of Middletown, Conn., said that on account of the lateness of the hour he preferred not to read his paper on the etiology of general paresis. He wished, however, to record the fact that in his series of 164 cases, in a community one-third the population of which was rural, he had found that the prominence of the various etiological factors certainly was at variance with that brought out by some of the previous speakers. He had become convinced that excessive alcoholism was an important primary etiological factor, and in the cases he had observed it occurred in over 54 per cent. In his community the negress paretic was far in excess of the white female paretic, in the proportion of ten to one. In 5 per cent. of his cases the mental symptoms had immediately followed an injury.

Etiology of General Paresis.—Dr. M. S. Gregory read this paper which he said was based upon a fragmentary résumé of his clinical experience gained during the past four years in the psychopathic wards of Bellevue Hospital. Over 1,000 cases of general paresis had been admitted during that time. The disease had represented 13 per cent. of the total admissions into those wards, and composed 21 per cent. of the total male, and 5 per cent. of the total female insane patients. The relative proportion of the sexes suffering from general paresis had varied from year to year. In 1903 there were more than six times as many male as female paretics; in 1904, the proportion was four to one. For the three years, the average had been five men to one woman. Thus the women represented about 20 per cent. of the paretics admitted. In at least a third of the patients, the histories obtainable were for obvious reasons not so complete as might be desired; many of the patients were foreigners, without any friends, and one had to depend entirely on the history as given by the patient, who was frequently brought to the hospital following an episodic attack, and was, as a rule, in a condition of extreme mental confusion. Most of the patients admitted to the psychopathic wards at Bellevue came from the very lowest strata of society, and they, as well as their friends were usually too ignorant to give a complete history. Owing to the short time the patients remained in the hospital, the opportunities for obtaining adequate histories were necessarily limited. In view of those difficulties, therefore, the histories of 250 cases had been selected for analysis. They were those of patients admitted consecutively, and did not include those in which the defects spoken of had been marked. In the 250 cases analyzed, the age of the patients ranged from 18 to 65 years, the majority being in the fourth and fifth decades of life. Several were under 22 years, the youngest being a woman of 18 who had contracted syphilis at the age of 13. The oldest was a man of 64. Of this series, 75 per cent. of the patients were married. Almost all nationalities were represented. There were 76 native born; 70 Germans, 48 Irish, and 35 Hebrews; two were negroes and one Japanese. Laborers were naturally the most numerous. Among the better class of patients were five actors, three merchants, two physicians, and two lawyers. A family history of mental disease was obtainable in about 20 per cent. of the patients. In 12 per cent. the family history showed various disorders, such as Parkinson's disease, hysteria, epilepsy, neurasthenia, etc. In about 25 per cent. of the patients there was a distinct history of alcoholic abuse. In six cases, the intemperate use of alcohol was given as the chief cause. In 12 cases the assigned cause was traumatism to the head; in 6, overwork; in 4, grief and business worry; in 3, "stomach trouble"; in 3, rheumatism; and in one, grippe. A positive history of syphilis was obtained in 99 of the male patients; about 45 per cent. In 33 others there was a strong presumptive evidence of syphilis. In 16 cases, in which specific disease wes denied, there was a history of repeated miscarriages or sterility in the patients' wives.

In addition, several presented superficial scars and bone enlargements. Twenty-one gave a history of chancroids, or repeated urethritis. Among the female patients, a positive history of syphilis was present in six cases; 20 per cent. Two gave the history of an initial lesion, and in four the husbands admitted having infected their wives. In nine, there was a history of repeated miscarriages, with a confession on the husbands' part that they had had chancre "many years previously." Two patients had had chancroids and gonorrhea. If these incomplete histories could be regarded as indications of luetic infection, the percentage of syphilis in this series would be 80 in men, and 56 in women, the average for all being 78. In these 250 cases, the shortest period of development of paresis after the initial lesion of syphilis was 5 years; the longest, 36 years. In recapitulation it seemed that clinically speaking, three factors were necessary for the development of paresis, and they were, in the order of their importance; (1) hereditary or constitutional predisposition; (2) syphilis; and (3) an exciting cause, such as stress of life, mental or physical strain, trauma, or intoxications of various kinds. The prognosis of a true case of paresis, Dr. Gregory believed, was uniformly fatal. He was inclined to think, however, that the general tendency had been to give too gloomy a prognosis as to the rapidity of the progress of the disease, for at least some of those patients. One could never be certain as to remissions.

Cholera	..	..
Total	2,799	252

Leg Ulcers.—For obstinate ulcers that resist the simpler plans of treatment, H. A. Pulsford recommends Unna's zinc-gelatine dressing. This, he says, is made in the following way: Daily wet dressings of acetate of aluminium or boric acid are used until all sloughs have come away, and the floor of the ulcer is smooth and clean. Then the skin of the foot and leg is thoroughly scrubbed with hot water and tincture of green soap; after drying, alcohol is applied freely, and the skin is again washed in a solution of bichloride, 1-2000. The next step is the application to the skin immediately surrounding the ulcer, and to all eczematous surfaces, of a layer of Lassar's paste, without salicylic acid. The ulcer is thickly covered with subnitrate of bismuth or any unirritating powder, and a gauze bandage is smoothly applied from the toes to the knee. Upon this is spread with a paintbrush a layer of the hot zinc-gelatine paint, which has the following formula: Oxide of zinc, 8 parts; gelatine or glue, glycerine, each 5 parts; water, 22 parts. When first prepared, it should be kept at the boiling point in a closed vessel for half an hour, and it should always be sterilized in the same way just before using. Over the paint is put another layer of bandage, and over that a second coat of paint, continuing in the same way until from four to six layers of each have been applied. It dries in from six to twelve hours, but is always more or less elastic. It should be left in place until a spot of discharge shows through just over the site of the ulcer, which will happen, according to the quantity of discharge, in from four days to three weeks. The formation of granulations and the spread of epidermis goes on rapidly under this dressing, and often results in a comparatively speedy cure, even when the ulcer seems hopelessly indolent. As a method of treatment it is almost universally applicable, doing good even where there is an extensive loss of tissue to be filled with granulations and covered with epidermis. In the larger ulcers, where skin-grafting is resorted to, it is an ideal dressing to apply after the grafts have taken.—*Journal of the Medical Society of New Jersey.*

Milk and Scarlatina.—Alice Hamilton presents the folfowing conclusions: The literature of milk-borne epidemics of scarlet fever contains many which are (a) based on insufficient evidence as to the agency of milk in the dissemination of the disease; (b) based on the erroneous belief that a disease in cows is capable of causing scarlet fever in man. The disease in cows supposedly responsible for scarlet fever in man is ordinary cowpox, and the disease in man supposed to be caused by it is either septic fever from infection with pyogenic organisms or coincident scarlet fever. There is no good evidence that milk from diseased cows can cause scarlet fever in man. After rejecting many reports of milk-borne outbreaks of scarlatina there remains a fair number which are above criticism, and which apparently prove that milk is a good culture medium for the scarlet fever virus, and is the most frequent agent of indirect infection in this disease.—*American Journal of the Medical Sciences.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service duringthe week ending January 20, 1906:

CLEAN AIR.*

By T. MITCHELL PRUDDEN, M.D.,

NEW YORK.

From the beginning to the end of his life three things man must have, whatever else he may lack. These are air, water, and food. Under natural conditions the air is everywhere abundant; the supply of water is bountiful or may be obtained in nearly all regions naturally fit for human habitation. Under almost all circumstances the consumer or somebody else must work for his food.

But the securing of these three essentials of life becomes more complex and difficult as men herd together in communities, and especially in great cities. The air gets contaminated by enclosure in the confined spaces in which we live. The water becomes scanty from the large local demands upon a limited supply, or unwholesome by its pollution through community waste. Food grows costly by the increase in population and the grouping of people who are not themselves food producers; it becomes deficient or harmful through the rapacity of its purveyors and the ignorance and intemperance of its consumers.

Of these three essentials to life it is the air alone which now concerns us. We need not dwell upon the harmful products of human waste in the air, nor upon the various other ways and forms of air contamination which involve its gaseous constituents. These have been the subject of extensive studies, and their nature and significance are well known. The common problems of ventilation find adequate treatment in the standard treatises on hygiene and sanitation.

But there is another kind of air contamination which has not hitherto received as much attention as its importance justifies, namely, floating dust, to which this paper is largely devoted.

Dust as an inciter of disease has long been recognized in occupations which involve the setting free in the air of large quantities of finely pulverized material. Such trades as certain forms of mining, wool sorting, stone cutting the making of certain pigments and chemicals are placed in a class by themselves as especially dangerous occupations.

But it is comparatively recently that the significance of floating matter in the air in relation to the health of the people at large has been realized, and the accumulation of this new lore is closely linked with the development of our knowledge of bacteria and other minute infectious agents.

It was clear enough from the beginning to the devotees of the new science of bacteriology that among these minute commensals of man only a few were of sinister import. But to most physicians and to the public, bacteria were things to conjure with, and all shared in the bad repute of the few which were demonstrably pathogenic. So for a time the mere presence of many bacteria in food or water or air was looked upon as a serious menace.

But with the discovery of one after another of the inciting germs of various infectious diseases, a knowledge of their sources and the conditions under which they flourish or are destroyed, a more intelligent and discriminating viewpoint was reached. Men came to dread the forms which are harmful, and set about finding means to curtail their ravages, and left the remainder, the great majority, to their own devices, or made them the subject of curious and fruitful biologic study.

It soon became clear that the infectious microorganisms are conveyed from an individual harboring them, either directly by personal contact or indirectly through some contaminated intermediary, or through some solid or liquid used as food or drink, or, finally, through the air in the form of visible or invisible dust.

We leave, as not bearing directly upon our theme, the various modes of conveyance of infectious agents by immediate contact and through contaminated food and drink, and turn to aerial infection.

Infectious material, depending as it always does upon microorganisms of some sort, can only pass from one individual to another through the air as particulate bodies. Thus the study of the physical conditions under which fine particles can be disseminated in the air, how long they can remain in suspension under various conditions, and how these conditions affect the viability and virulence of infectious microorganisms, has become of great importance.

It was early learned that bacteria are not readily separated from fluids or moist surfaces by air currents, and that the exhaled breath is practically germ-free even in those suffering from communicable infectious diseases. It was found that many microbes are killed by drying, by sunlight, by immersion in water; or if not killed, many pathogenic forms are greatly reduced in virulence.

On the other hand, a host of careful studies has been made on the various safeguards of the body against the entrance of microorganisms, and a flood of light has been let in upon the subtle and highly effective processes through which invading germs of all degrees of virulence are safely disposed of within the deep recesses of the tissues, when by some mischance they have overcome the barriers.

The early conception of the risks of aerial infection is clearly exemplified by the story of the Lister spray and its various modifications, which at one time dominated the field of practical surgery. It was then the endeavor at all hazard to remove the possibility of bacteria of any kind which might be floating in the air, entering the open wound. It did not matter much where these came from. All bacteria looked alike to these early devotees to antiseptics.

But the remarkable capacity of the living tissues to kill and safely dispose of most bacteria soon impressed itself upon the surgeons through practical

*Read before the Practitioners' Society, January 5, 1906.

experience and the studies of the laboratories. They began to realize that the direct conveyance to the wound of a few forms of well-known germs from an outside source of infection is a far more serious menace than the indirect conveyance even of the same organisms which have been subjected to the unfavorable influences of drying, sunlight, etc., usually involved in the formation of dust. Thus it is that most surgeons to-day, having secured what they consider reasonable cleanliness in their operating rooms, disregard the air as a risk, and concentrate their attention upon direct sources of infection, such as hands, instruments, dressings, the seat of operation, etc.

Similarly, the alleged sources and frequency of aerial infection through the respiratory apparatus began to be accepted with more reserve as knowledge grew on the one hand about the nature and vulnerability of infective microorganisms and on the other about the self-protective capacities of the human and animal body. Finally, one of the most significant features in infection secured recognition, namely, that the simple presence or growth of infective agents in the body does not suffice for the incitement of disease unless a series of favoring conditions of the body itself be present. This prerequisite to infection, sometimes very subtle, and often not yet at all clearly understood, is named predisposition or susceptibility, and its final recognition has contributed largely to the juster estimate of the common risks of infection, as well as to the brightening outlook for the suppression of many serious maladies.

Thus the drift of discovery and the perspective which our present outlooks furnish, lead to a more critical and a somewhat chastened estimate of the actual risks to which we are commonly exposed from floating matter in the air of inhabited regions.

Still, when all is said in favor of the saner view which the knowledge of to-day may justify, the proper disposal of infective secretion and the removal of dust which gathers in the close and often crowded spaces in which many pass a large share of their lives is of great importance, and its neglect has a direct bearing upon the increase in respiratory diseases which statistics show.

Let us therefore look more closely at some of the more recent studies on dust and its significance.

We seldom realize what an enormous number of dust particles may be floating in the air of enclosed places which in diffused light seems clear and pure. But let a beam of sunlight fall through a small opening into the air, or cast a powerful electric light across the dusty space. Then an incredible number of minute particles may be seen dancing about, forming indeed a sharp luminous pencil made up of the reflected rays thrown from each tiny mote.

How numerous these particles may be even in inhabited places, it is not easy to determine. But various methods have been devised for counting them.

Dust-containing air in measured volumes has been caused to bubble through fluids, the latter evaporated, and the particles weighed or counted. It has been filtered through cotton and the amount determined. It has been blown against glass plates covered with adhesive material, and thus an approximate estimate arrived at.

The most accurate and ingenious method of dust analysis is that of the English physicist Aitken, who has devised an instrument called the Aitken dust counter, by which we may determine the exact number of particles in any given volume of air.

It is worth looking at for a moment, this ingenious instrument of the English scientist. It is well known that when the air is fully saturated with moisture and is then suddenly cooled, the watery vapor condenses as fog or rain. It is not so well known that in the formation of fog or rain a particle of floating matter in the air, that is, of dust, forms the nucleus upon which every drop or droplet is condensed Now, it occurred to Aitken that if he could reproduce experimentally, in a measured volume of dusty air, the conditions under which fog forms, and then could count the fog droplets, he would know how many dust particles there were in the air; the counting of the fog droplets being easier than counting the dust particles, because they are much larger.

The "dust counter" as it was finally perfected consists of a small, accurately measured, air-tight chamber, connected with an air pump and with an arrangement for introducing small measured volumes of dusty air. The air chamber, saturated with moisture, is first charged with a measured amount of the air. Then with a sharp thrust of the air pump a partial vacuum is created in the chamber. The air expands, and as it does so suddenly cools, so that a fog droplet is formed around each floating dust particle. The operator is watching the illuminated interior of the chamber through a lens and can see the shining droplets as they suddenly flash into the field of vision and fall in a minute shower upon a ruled plate at the bottom of the chamber. Then, when all the fog droplets have fallen and the mimic shower is over, he counts the microscopic splashes, each one representing a whilom floating dust particle, and makes his simple calculation of the number which were in a thimbleful, or a breath, or a roomful of the dusty air. No matter how small the floating particles may be, the fog catches them every one.

I show to you Aitken's dust counter set up and ready for use.

Prof. Aitken has made many interesting studies of air under various conditions, and the revelations of his analyses are even more striking than those of the sunbeam, because they are expressed in figures. For example, he has estimated on the basis of counts with his instrument, that the devotee to the gentle cigarette may set free upon an unwilling environment at one full average exhalation, not less than four thousand million particles of smoke.

The number of dust particles in the air we breathe, even when very impure, is of course usually much less than this, and many factors must be taken into the account before one ventures upon a numerical statement of the average number in any given place. For example, the air out of doors may be largely cleared of dust by rain and fog. On the other hand, dry winds may sweep dust particles upward in vast numbers from the ground, and hold them suspended for hours upon the air, driven hither and thither in clouds of varying density. Again, the great volumes of relatively clean air moving across a dusty region may so dilute the impure air that the number of dust particles in a given volume is greatly reduced. Or they may be carried away altogether.

Finally, one of the most important of the physical agencies determining the number of dust particles at any fixed place is the gradual settling of the dust whenever the air is moving slowly or is still.

In his studies upon the floating matter in the air, Tyndall found that these myriad dust particles, if enclosed in a tube, soon settle upon its sides and bottom and the enclosed air becomes as clear and moteless as are the stellar spaces. This is, indeed, only a more refined form of the experiment which every housekeeper makes who closes the room after sweeping to allow the dust to settle.

Thus it is evident that when we are told that somebody has found so many thousands or millions

or hundreds of millions of dust particles in the air of some town or street or building, we may justly insist upon knowing the conditions of his analysis before we can concede any special significance to his figures.

What the effect may be upon the health of persons who breathe this more or less dust-laden air can be more intelligently considered after we have glanced at one most significant form of dust, namely, that containing bacteria or other kinds of microorganisms.

Microorganisms floating in the air as dust are sometimes single, more often in small clusters or masses joined together as they have grown, and are very apt to be clinging to some other forms of dust particles.

The number of microorganisms which the air may contain varies, like other forms of dust, with varying conditions. In the case of these, as of other dust particles, the actual number determined by analysis is of little value as expressing averages, unless the conditions are carefully recorded. In general it may be said that the out-of-doors air contains far less microorganisms than that in rooms where men and animals gather, because of the dilution constantly occurring from the vast volumes of clean air sweeping across the country.

There are two common methods of determining the number of living microorganisms in the air.

The first and most accurate is by allowing a measured volume of air to filter slowly through a tube of dry sterilized sand, which retains all the dust particles, microorganisms among the rest. The entire content of the tube is then planted in a suitable culture medium. The number of colonies of microorganisms which grow under these conditions is taken to indicate approximately the number of living germs in the measured air volume.

Here is the apparatus which we use for quantitative analysis of air. This is a vacuum cylinder so adjusted that when exhausted to a certain point on the gauge it will draw in ten liters of air, which passes through this tube partly filled with sterilized sand. Here is a culture plate after the operation, in which you see among the grains of sand the scattered colonies of various forms of microorganisms.

The second method of so-called biological air analysis consists in exposing culture plates of nutrient medium to the air for a definite time, and then counting the colonies which develop from the dust which has settled upon the surface during the exposure. Care is, of course, taken in this form of analysis to secure quiet places for the plate exposures, and the results, while not so accurate as by the first method, are still of value in comparative studies, provided the conditions of the observation are carefully noted. To record simply the numerical result of such an experiment is of little value, because the bacterial content of the air in still places is constantly diminishing by the settling of the dust particles.

Here is a series of culture plates which have been exposed for fixed periods to the falling dust of an inhabited room. You see the great variety of forms in the germs which have grown to colonies upon the surfaces.

But whether the air contains few or many living germs, their significance as regards the welfare of those who use it rests most directly upon the forms which are capable of inciting infectious disease. The others are harmful in just such manner as all dust may be harmful when in the air we breathe.

As was natural, very careful search has been made in dwellings, public conveyances, places of public assembly, hospitals, etc., for living pathogenic microorganisms. And the booty has been considerable. Tubercle bacillus, pneumococcus, streptococcus, staphylococcus, diphtheria, anthrax, tetanus, are among those recorded.

But, as we shall presently see many of the pathogenic microorganisms which have been found in inhabited places have been gathered under conditions which did not indicate that they were in such a finely divided state that they could have contributed largely to the risks of dust infection through inspired air.

We may now concentrate our attention upon dust within doors since it is here that the most serious questions arise relating to the maintenance of health.

We shall first look at some of the physical conditions determining the distribution of microorganisms in the air as dust.

While it has long been known that dust particles settle in still air so that under experimental conditions the air of a small receiver may become quite dust-free, it was not clear that a similar condition could be secured with floating microorganisms in living-rooms and places of assembly, since here, though tightly closed, the air is always astir, sometimes with currents of considerable force.

But some years ago Stern found in a small, tightly-closed, empty room, whose air he had charged with certain easily recognized bacterial dust, that within from twenty to thirty minutes the larger part, in from one and one-half to three hours almost all the bacteria, had settled to the floor, so that the air was practically germ-free.

It had commonly been assumed that in ventilation the air renewal would suffice to remove not only the vitiated air, but its floating particles as well. So Stern studied the effect of ordinary ventilation on the dusty air of his experimental chamber. He found that with ventilation sufficiently effective to change the whole volume of air four times per hour there was little gain over the clearing of the air by simple settling. On renewing the air six to seven times an hour he found some gain; while if the whole were changed ten times per hour, there was a rapid removal of the bacteria from the room. It should be remembered that under suitable conditions the air in a room may be renewed four or five times per hour without the creation of an appreciable draft. It is thus seen that in the ordinary effective ventilation of a room bacteria are not removed from the air to any considerable extent.

Another point of great interest is covered by the experiments of Stern. It has long been a popular impression that the opening of windows, especially when the wind is blowing, is effective in the removal of dust from rooms, even though this has already settled upon the open surfaces. Stern found that this is not the case. He studied the effect of air currents upon bacterial dust which had already settled naturally to the surfaces of floors, fabrics, etc., and found that even very rapid currents of air—six to eight feet per second—blown across such surfaces do not dislodge the bacterial dust in appreciable degree.

It follows from these experiments that the ordinary ventilation, however effective it may be in the supply of fresh air and the removal of gaseous contaminations, has no noteworthy effect in the removal of dust, either floating or at rest.

Indeed, if the fresh air introduced in artificial ventilation contains dust, with the slowly moving currents between the entrance and exits, the dust steadily falls, so that the rooms are actually settling basins in which dust, unless otherwise removed, continually accumulates.

These experiments show also that the hanging of

garments out of doors in the air with the expectation that infective agents will forthwith abandon them, is not to be commended. For unless such articles be brushed, or beaten, or shaken, or flap violently in the wind, bacteria are not largely removed.

Although, as stated above, various pathogenic organisms have been found in the dust of inhabited places, the fact that a large proportion of most of them are killed by drying and by exposure to sunlight, as well as confidence in the effective safeguards of the normal body, led to a widespread disregard of the risks of dust infection except in a few instances, among which the most conspicuous is tuberculosis. The pulmonary forms of this disease so frequently involve the discharge of large numbers of living bacilli that this risk was recognized, while in other infectious diseases it has been largely ignored.

But some years ago, Flügge investigated the fresh infective material which may be discharged from the mouth in speaking and coughing, and from the mouth and nose in sneezing. The results of these studies, carried on largely by himself and his assistants in Breslau, brought to the front a series of new and sinister possibilities of air infection. In brief, Flügge and his associates found that not only in sneezing and coughing, but also in ordinary speech, the secretions of the nose, mouth, and throat may be cast forth in considerable quantity for a distance of several feet, not only in the form of visible droplets, but as a more or less abundant, invisible spray, which may remain suspended for from half an hour to several hours, and may be carried for long distances on such slowly moving air currents as are common in inhabited rooms.

The method by which these results were obtained was simple. The mouth and throat of the subject was rinsed with a small amount of an emulsion of a harmless bacterium—frequently the *B. prodigiosus*—and he was placed in or in front of a small sterile cabinet, in various parts of which culture plates were exposed. At the end of the seance, after speaking or coughing or sneezing, the dust and invisible spray were permitted to settle on the culture plates, where later the colonies which had grown were counted.

There is much difference in individuals as to the extent of dispersal of material in speech, as was shown by declamation into the cabinet by various persons. It is rather sharpness than loudness in speech, and especially the enunciation of certain of the consonants, such as t, k, p, b, f, which give rise to the most generous ejection of the secretions. There is a marked difference in individuals who cough, depending in part upon the vigor of the act, the character of the secretions, and the position of the lips. It was found that most of all in sneezing the air may be widely contaminated.

Not only was it possible to infect culture plates with microorganisms taken into the mouth with experimental intent, but patients with tuberculosis were so placed as to cough and sneeze in enclosed places in which animals were confined, with the result of tuberculous infection of the exposed animals.

These studies of Flügge and his followers have thus shown, among other things, that in the immediate vicinity of persons whose mouths harbor pathogenic microorganisms there is a varying but often considerable risk of the direct conveyance, especially in coughing and sneezing, of fully virulent infectious material, not only in the form of visible droplets, but as invisible spray.

Later studies of de Leon, Hamilton, and others, have emphasized the importance of this floating spray in the conveyance of streptococci and other pyogenic organisms from infected mouths during surgical operations, and the incitement of fresh infections in hospital wards and elsewhere.

While in general it may be said that the directly infectious zone does not usually reach beyond two or three feet, it is still to be remembered that so minute are the particles often expelled in enormous numbers in the commonly invisible spray of sneezing, that these may be carried for many feet on air currents as slow as those involved in ordinary ventilation or such as are invariably present in inhabited rooms.

Such minute particles, moreover, which harbor microorganisms not killed by drying, may ultimately form infectious dust so light that when wafted into the air by the movements of persons or by improper methods of cleaning, they may remain long suspended in suitable form and condition for inhalation.

The time during which bacterial and other dust remains suspended in the air is naturally dependent upon the weight of the particles, so that in forming an estimate of the risks of infection from floating dust, one has to consider not only the physical characters—size, weight, aggregation, etc.—of the various pathogenic microbes, but also the conditions under which they gain access to the air.

In this connection the critical studies of Flügge and his associates have brought to light some interesting points.

In the first place, it has become clear that not all the infectious material which may be cast out of the body as sputum is always readily and speedily transformed into dust. In the drying of the mucus with which much of this material is mingled, a process ordinarily rather slow, the bacteria are closely imprisoned so that only under certain conditions, such as the rubbing and beating of soiled clothing, the shuffle and tread of feet over contaminated floors, dry sweeping, and the like, is the excretion sufficiently comminuted to float in the air as dust. Even when this is the case, it has been found that a large part of such pulverized excreta is still in too large particles to remain long suspended on the air.

This condition of affairs was not appreciated in the earlier studies on dust infection, and in many instances the material called dust, collected in various places for analysis, was evidently not in such form as would have remained long in suspension. Thus it is that while the earlier identification of various pathogenic microorganisms in the dust of rooms was correct, the inference as to the constant risk of dust infection in such places was frequently at least somewhat overestimated.

Many studies have been made on the transportation of dry germs in floating dust, especially indoors. Such air-borne germs readily pass from room to room on the ordinary air currents. If doors are closed, they make their way through cracks and keyholes. They are wafted from one story upward to the next, and readily find their way into closed wardrobes, bureau drawers, and between the leaves of open books.

The effect of walking over floors on which bacteria-laden dust has settled is to set large numbers astir, but in still air these do not commonly rise more than a few feet and then slowly settle back again. Dry sweeping of such floors sends clouds of germs into the air, contaminating it in every part.

We have thus seen that the amount of dust in the air which we breathe is not only constantly varying, but that its significance in relation to health is closely linked to the sources from which it is derived. Among the microorganisms which form a constant part of the dust in inhabited regions, it is those which are derived from men and animals, themselves the subjects of infection or harboring patho-

genic microorganisms which are of dominant significance.

Let us now glance at some of the ways in which the body is protected against the entrance of dust and the means by which it is disposed of when it does pass, as is frequently the case, even the most effective barriers.

In normal breathing through the nose, the air impinging upon the moist surface of the tortuous passages loses a considerable part of its dust and bacteria. In the throat, larynx, and trachea, a similar clearing occurs, so that at the end of inspiration the air has been so far freed from its floating particles that it emerges in the expiration practically dust and germ-free.

If the nasal pasages are not normal, or breathing through the mouth is practised, the air contamnations may pass more deeply into the recesses of the lungs, or may still remain to a certain extent suspended in the expired air.

Many of the dust particles which may lodge upon the walls of the deeper air passages are swept upward by the ceaseless ciliary movement and cast out, as are the secretions and dust accumulations from the nose and throat. The growth of many microorganisms is inhibited by the mucus of the air-passages. Many inert dust particles which are taken into the tissues at the tonsils or in the deeper recesses of the air tubes are carried in the lymphatics to places of temporary or permanent deposit. Many microorganisms within the tissues are destroyed by phagocytes or by the body fluids.

Thus it is that although large numbers of dust particles may enter the respiratory passages at every breath, the larger proportion are usually safely disposed of, most of them through the secretions of the throat and nose.

It has long been known that a certain number of inert dust particles from the inspired air, in spite of the tortuous and narrow passages which they must pass in the deeper recesses of the lungs, do reach the air vesicles, from which they may be largely removed to the adjacent tissues or to the nearest lymph nodes.

Whether living bacteria can reach the air vesicles under the ordinary conditions of respiration, is a question much discussed and has given rise to many painstaking researches. One group of workers has concluded that the lungs, except for the larger air passages, are usually germ-free. On the other hand, many have concluded from equally careful studies that the lungs of both men and animals often, if not always, contain a moderate number of living microorganisms. The technical difficulties in this research are so great and the conditions under which they have been undertaken are so various, that this difference of opinion is not surprising.

Without attempting to marshal the evidence adduced on both sides of the question it appears that in most of the earlier studies on the artificial introduction of living microorganisms into the lungs, the time which was allowed to elapse between the introduction of the germs and the examination of the lungs was too long, so that the possibility that the lungs might rapidly dispose of germs lodged in their deeper recesses was overlooked.

In fact, it has been found that in experiments in which animals are exposed to an atmosphere laden with bacteria-containing dust or spray, if the animals be killed at once after the exposure, living microorganisms may be found even in the deepest portions, while if even a short time be allowed to elapse they will have entirely disappeared.

While, however, in the air passages and lungs we have a most efficient protective mechanism against the entrance and permanent lodgment under ordinary conditions of both inert dust particles and living microorganisms in such situations as would involve serious damage to these delicate organs, it should be remembered that the efficiency of these safeguards may be greatly diminished if they are overworked and abused.

The lungs of practically all persons who live indoors contain a considerable amount of soot, which blackens them. The irritation incited by this foreign stuff leads in most adults to some part of the lungs becoming dense and useless. The overworking of the delicate mechanism for filtering the foreign matter out of the lymph flowing from the lungs to the interior blood channels leads to serious damage of this mechanism and to an increased vulnerability to infection which the healthy body should and could resist.

These conditions resulting from excessive dust inhalation are not necessarily obvious through illness or apparent reduction in vigor. But in the long run, with many other offenses against personal hygiene, they are enough now and then to swing the balance toward disease and death.

There can be no doubt that various forms of catarrh of the nose and upper air passages, if not directly incited, are favored and perpetuated by the inspiration of dust-laden air.

Under these conditions, too, several forms of disease-producing bacteria find favorable conditions for continuous growth, while the discharges from such infected regions afford a perpetual source of widespread distribution.

It is not necessary for us to enter into the question much discussed of late, whether infective bacteria which enter the body by the inspired air commonly reach the lungs directly through the air passages, or whether in many instances they may not enter through the tonsils or the gastrointestinal canal, reaching the lungs by way of the blood or lymph vessels. The necessities for cleanliness in the air are the same in either case.

Perhaps the most common of the pathogenic microorganisms to be widely dispersed in the air as floating particles are the streptococcus and staphylococcus, which are apparently frequently concerned in the incitement of colds and of the lamentably frequent catarrhs. So general is the dispersal of these organisms and of those inciting influenza and pneumonia, that they are now generally recognized as regular denizens of the mouths of dwellers in towns.

The experience of those who come home to the cities after a summer of the most varied exposures in germ-free air without colds or other disturbances of the respiratory apparatus, only to inaugurate the winter with a bronchitis or influenza, is evidence of the vicious conditions in public conveyances and places of assembly.

Some slight exposure to draughts, overexertion, indiscretion in eating, and various other slight departures from healthful conditions, apparently suffice when these germs are present in virulent form, to precipitate an illness which often shadows the winter if it does not lead to serious or fatal disease.

It is clear to-day that in one group of infections, of which typhoid fever and cholera may be taken as types, the risks of the transmission of the infective material in floating dust are slight. In another group in which direct contact of vulnerable surfaces with infective secretions or exudates is requisite for communicability, such as syphilis, most wound infections etc., aerial infection may be left largely out of account.

On the other hand, in the exanthemata we have the clearest examples of aerial transmission of the

infective agents, though these are as yet unknown and can be guarded against only indirectly, or directly in the most tentative fashion.

Thus we have left the great and significant group of communicable diseases usually associated with the discharge from the mouth and respiratory organs of infective secretions and exudates in which the fact of aerial transmission is clear and frequent In this group are influenza, whooping-cough, pulmonary tuberculosis, diphtheria, cerebrospinal meningitis, and the various forms of exudative infectious pneumonia. It is in this group that many complex and urgent questions of prophylaxis center. Each of these diseases presents special conditions and individual problems.

For in order to gain a just estimate of the aerial communicability of any infectious disease in which the clinical evidence is not clear and abundant, it is necessary to consider the portals of entry of the special infective microorganism and the ways in which it may leave the body; its capacity for resistance to drying, sunlight, heat, cold, etc.; the condition in which it is given off, whether in fine particles or in masses more or less mingled with exudate which may materially modify its capacity for suspension in the air as dust.

We know that the tubercle bacillus may remain alive and maintain its virulence for long periods and under all conditions necessary for its complete desiccation and the grinding of the secretion which contains it into a powder so fine that it floats for a considerable time in the air. Similarly, though not to the same degree, the diphtheria bacillus, streptococcus, and staphylococcus resist drying for considerable periods.

On the other hand, the pneumococcus, the influenza and plague bacilli, and the diplococcus of cerebrospinal meningitis, like its relative the gonococcus, are all readily killed by drying.

The recent studies of Wood on the destruction of life in the pneumococcus by drying are most interesting in this connection.

But the capacity of a pathogenic microorganism to resist drying as a factor in aerial infection has become less significant since we have learned of the widespread diffusion of bacteria in the air by spraying in coughing, sneezing, etc., from the infected nose or mouth. Thus it is that the clinical evidence of communicability in the infectious respiratory diseases is not only sustained but largely extended by the direct studies upon the infective organisms themselves.

We have abundant evidence of the communicability of the air-borne infective agent in pulmonary tuberculosis and this has been generally accepted. We have quite as valid evidence of communicability in various phases of pneumonia, in influenza, in whooping-cough, and in epidemic cerebrospinal meningitis. But this has not yet become a part of the common professional belief, so that still in hospitals, asylums, and private practice, the necessary precautions against aerial communication are not enforced.

When we come to sum up the real risks from dusty air to which one is subjected indoors under the ordinary conditions of life, particularly in cities and towns, we see that they are very variable and depend upon a great many conditions.

There is more or less dust wherever man goes. It is usually most abundant and significant in densely inhabited regions and especially indoors. Under many circumstances the dust is moderate in amount, does not contain infectious material, and so forms one of the many conditions in modern life which, though detrimental to health, are not positive and direct incitants to disease.

The protective mechanism of the body is so nicely adjusted to the usual conditions that a moderate amount of dust in the air inspired is readily and safely cast off or otherwise disposed of.

On the other hand, there are many conditions under which the dweller in modern towns finds himself, in which the air is heavily and almost continuously charged with dust, some of it undoubtedly derived from the infectious waste of diseased persons who, through spitting or unguarded sneezing or coughing, or in other ways, have contaminated the air. But whether under these unfavorable conditions one shall suffer from his exposure to these various disease incitants depends in the largest measure upon his physical condition. If the natural safeguards against infection through his respiratory organs are in good working order; if he be not predisposed through some general physical disability to the incursions of such infectious microbes as may have survived the adversities of drying, sunlight, etc., to which his particular dose of dust has been subjected —then, indeed, he may for months and years together sustain without much obvious damage the burden of dusty and even infective air.

This is in fact the good fortune of most city dwellers. But now and then, here and there, with one or another of the crowd, the adverse conditions fit together and one or another falls victim to preventable dust disease.

If now we turn to those individual precautions and public measures by which we may strive to reduce the risks of aerial infection through floating dust, it is at once evident that there are two distinct parts to the problem: *First,* the prevention of the distribution of infective material in such condition that it floats in the air or may be converted into dust; and, *second,* the practice of such methods of cleaning as shall ensure the removal or destruction of infective or other dust from inhabited places and especially from dwellings and indoor places of assembly.

First, as to the distribution of infective material. It is fortunate that, so far as we know, very few of the infective microorganisms flourish or even survive for long periods outside the bodies of men and animals. Some, indeed, such as the germs of tetanus and anthrax, in the form of spores, may remain alive for an indefinite time; but dust infection from these sources is extremely uncommon and may, for our purposes, be left out of the account. So also we need not consider here the infective agents which are not likely to incite disease of the respiratory organs, such as the typhoid and cholera organisms.

We cannot discuss, except in a general way, the exanthemata because we do not yet know just what their inciting agents are. It is probable that they are extremely minute, air-borne organisms and that infection takes place through the mucous membranes of the nose, mouth, or respiratory passages. If this be true whatever measures are efficient against the distribution of infective dust in general will be, in a measure, useful with them also, since however minute they may be they must be particulate bodies and subject to the general laws of dust transportation and subsidence. However, in the case of the most important of the exanthemata—smallpox—the protective action of vaccination has largely reduced the risks from aerial infection.

Now in this class of diseases, which we may regard as most important from our present point of view, are, as we have seen, influenza, whooping-cough, pulmonary tuberculosis, diphtheria, various

types of pneumonia, various forms of nose, mouth and throat lesion associated with streptococcus and staphylococcus, and cerebrospinal meningitis. In nearly all of these diseases exudates are cast off in varying amounts which contain virulent micro-organisms.

It is clear that the golden moment for prevention is when these various infective excreta are cast out of the body. The methods for preventing the distribution of these are so well known that we need not rehearse them here. Two points, however, may be briefly touched upon.

First, the careful disposal of sputum is seldom practised to-day except in the case of pulmonary tuberculosis. Every reason for care which applies to this disease is pertinent also in nearly all of the others. Second, the wide and obvious distribution of infective stuff in a fully virulent condition by coughing and sneezing is still ignored. If, whenever it is practicable, the obvious precaution were taken to hold the handkerchief before the mouth and nose during these acts a very important advance would be secured in the prevention of the infectious maladies which we are now considering.

For this material, if it does not find its way directly to the respiratory organs of others, soon dries in the air and is then floating dust instead of floating spray, or dries upon the surfaces to which it has settled and then is subject to the various physical conditions under which it is ground into a powder.

The filthy and wholly unnecessary habit of spitting on the floors in public places and in many dwellings is still widely practised. The few instances in which legal measures have been resorted to to suppress this nuisance and menace to the public health have already led to a noteworthy sentiment against promiscuous spitting.

But in order to secure important results, offenders must be ceaselessly and relentlessly pursued. An occasional arrest at long intervals is of little value and whatever official shall undertake to do his duty in the matter will have to realize that the fish who come to his net are as likely as not to be quite exalted political personages, as well as others in fashionable attire.

But education in cleanliness is a slow and discouraging undertaking and involves a far more radical reform in the sense of decency than the law alone can ever secure. Moreover, under the most favorable conditions there will always be a considerable dispersal of infectious material in closely crowded communities.

Thus we are led at last to a consideration of those methods of cleaning and disposal of dust which our knowledge of the infectious diseases makes imperative and which our studies of dust have made entirely practicable.

In all living rooms the conditions are favorable for a continuous accumulation of dust. If there be an adequate ventilating system the so-called fresh air in our cities usually enters more or less charged with soot and other forms of dust. This in part settles upon the horizontal surfaces before the contaminated air leaves the room through its proper exits. The ordinary gas burners furnish an enormous number of minute smoke particles invisible to the eye. Shoes and garments worn upon the streets and in places of public assembly bring into dwellings large quantities of material of the most objectionable and often filthy or infectious origin, most of which presently takes its place with the rest of the floating and falling dust. Add to this the sprayed secretion in coughing and sneezing, the wear and disintegration dust from persons, garments, furniture, carpets, hangings, etc., and one has framed but an incomplete inventory of the aerial flotsam and jetsam of an inhabited room.

While dust in a condition to do harm is always floating in the air it is important to remember that in the long run dust is always falling. It is true that when the particles are small and light they may be temporarily swept upward or borne along on air currents so that the effect of gravitation seems to be temporarily suspended, but the steady pull is downward and they always come to rest on the lowest available surfaces. Thus it is that in enclosed places the air always tends to free itself from dust.

If some time in the twenty-four hours the room can be shut up so that the air is fairly still the dust will practically all settle to the horizontal surfaces. If now we can remove it from these without stirring it into the air again we may, once in the day at least, start with relatively dust-free and germ-free air.

If the rooms are uncarpeted it is easy, by the use of moistened sawdust, to sweep them with comparatively little stirring of the dust. Then if two or three hours be allowed to pass with the rooms closed or still, whatever dust may have been stirred in sweeping will have again settled and by the use of moistened mops and moist or dry cloths it may all be removed.

But as a rule this is not done. Dry sweeping is largely practised and this is, under all circumstances, an abomination. Then usually the so-called dusting is done before the proper time has been permitted for the dust to settle. Then, further, the most silly performance conceivable is indulged in, namely, instead of removing the dust, which has settled, in a safe and easily managed condition, it is set afloat again by dry dusting. Nothing is accomplished by this except to get the dust off from the shiny surfaces for a short time and to get it in a condition to do the greatest possible harm through its inhalation by the unfortunate victims of that most fatuous of housekeeping fetishes, the feather duster.

There appears to be no good reason why the simple procedures above recommended should not always be followed in those places of public assembly in which, at present, the risks of dust infection are most constant and most threatening. Such places are theatres, churches, clubs, schools, court rooms, factories, stores, office buildings, hotels, railway and trolley cars, hospitals, asylums, and the numerous rooms in which artisans are crowded together engaged in occupations involving the development of various forms of dust.

If all such places in which it is practicable were properly swept *at night* after their occupants had left them, and then closed until mornig, when, before the people returned, with moist mops and dust cloths the floors and all horizontal surfaces were intelligently cleaned, with the purpose of removing and not simply stirring up the dust, there would be an immediate and far-reaching reduction of the dangers from infectious and other floating matter in the air.

Of course in private dwellings the methods of keeping the air free from dust which commend themselves in public places are not wholly applicable. Sweeping cannot be done at night, and the elaborate furnishings which are in vogue make special procedures necessary. The scope of this paper does not permit me to enter upon these in detail. But here as well as in all carpeted places the use of moistened shreds of paper thrown upon the carpets and carried forward with the broom will be found most effective in gathering and holding the dust.

The vacuum process in cleaning, if this be properly administered, affords a valuable means of getting

safely rid of a considerable amount of dust which has gathered upon carpets, rugs, and other surfaces. But the plants for this purpose have not yet been widely installed, and in daily routine it is wisely combined with other and supplementary methods of dust removal.

The carpeting of places of public assembly involves the presence of filthy and dangerous dust in the air, and until proper notions of intelligent cleanliness shall prevail the frequenters of such carpeted places will pay the penalty of their indulgence by attacks of disease of the respiratory organs which might readily be avoided.

The chief error in the present situation is that these homely but necessary offices of daily cleaning are not intelligently directed and supervised, but are placed in the hands of ignorant persons, entirely willing and often furiously devoted to their tasks, but who are seldom advised as to the necessity for the removal, not the stirring up, of dust. The more devoted they are the more often do they appear with the feather duster to set astir the dust which for the moment may have settled to some inoffensive place upon the furniture or floor. The result is that in some of the most carefully and expensively administered places—the great city clubs, for example—the members are perpetually served with the most obviously dust-laden air.

It is a curious fact that in a large proportion of the various places of public assembly the only systematic and effective measure of removal of the often infectious dust is by the mucous membranes of the nose, mouth and upper air passages of the persons who frequent them. One inclined to figures may readily estimate the efficiency of this method of dusting a theatre, for example, if he considers that at each breath the average person takes into his respiratory organs about thirty cubic inches of air. This he immediately discharges, wholly purged of its dust and microorganisms which he retains and must presently dispose of as best he can. But the air of the theatre is free of them.

The trouble is that while some of us are mighty particular about the cleanliness of our clothing, of our food and drink and the utensils in which these are served, and the exterior of our persons, we make no protest as we bear away upon the delicate membranes of our respiratory organs, from places of public concourse, the pulverized excretions of the filthy and diseased. Fancy our reproachful protest should the breakfast of to-day be served upon utensils marked with the remnants of yesterday's repast! But in a considerable proportion of cases in theatres and court rooms, in offices and public conveyances, in factories and stores, the floating dust of to-day is pregnant with the spit of yesterday.

The tendency of the hour in cities is to cram people into box-like apartments in great, many-storied buildings. And while, in administering to the welfare of the tenants of these vast caravansaries in lighting, heating, plumbing, ventilation, etc., the most refined requirements of the day are not overlooked, it still remains a fact that against the growing menace of floating matter in the air there is seldom any safeguard. Whatever degree of intelligence the janitor and his satellites may bring to their tasks the tenant may thank his good fortune for. But he usually clears his air of dust by his own mucous membranes, and he is usually the victim of chronic nasal or pharyngeal catarrh.

Would it not be well to release our delicate and valuable breathing apparatus from the burden of the disposal of this contribution from all manner of men, animals, and things, and give it a chance to settle at least once a day and then, once for all, get rid of it?

Of course this does involve the higher education of the housekeeper and a certain degree of trained intelligence in the executives—and the total abolition of the feather duster.

Of course in time the steady breathing of dust-laden air does free it from its floating matter, but it is an expensive method of housekeeping and the final account is made up in the disease and death records of the Health Department.

It seems a little difficult for laymen—and for many physicians, too, for that matter—to realize that there is no mystery about the way in which the agents which incite infectious disease are conveyed from one to another. The tendency seems to be to look for some intangible miasm, some vague, half personified agency which moves about with sinister intent, and to insist that the only way to remove the risks of aerial infection is to use some more or less choking or bad smelling disinfectant, or to saturate the air with a highly aromatic vapor which may mask, but does not destroy, bad odor due to faulty sanitation.

The fact, however, is that a large part of the so-called disinfection might be replaced, to advantage, with proper methods of sweeping, dusting, and mopping, if these were not so simple and commonplace and all could and would realize the significance of floating dust in the conveyance of infectious agents.

But while the initiative and the moral support in such measures for safeguarding the public health must come from the medical profession, I should still have hesitated to direct the attention of the Practitioners' Society at such length to a subject so elementary and so time-worn, were it not that a specific and urgent responsibility appears to rest upon all physicians in the protection of patients in the hospitals to which they minister, against the dangers of infectious and other dust.

The large number of cases of secondary infection acquired in hospitals, and particularly in children's hospitals and asylums, is fairly appalling, especially in the winter months, and, while many factors are doubtless concerned in maintaining this sinister condition, there can, I think, be little doubt that aerial infection through dust-borne microorganisms plays a large and significant part.

The general aspect of most modern hospitals is one of extreme cleanliness, and certainly in most instances there is no lack of attention and willing service in the daily routine of cleaning. But, in fact, except in the case of tuberculous patients who may be admitted to general hospitals, there is no systematic attention paid to the directly infectious zone which surrounds each patient suffering from an infective disease of the respiratory organs, formed by the dispersal of secretions through sneezing and coughing.

Furthermore, the processes of daily cleaning are almost never specifically directed to the absolute removal of the finer dust.

I do not think that those concerned with the so-called dusting of hospital wards realize how large a proportion of the horizontal surface on which dust settles is made up by the floors and beds. A few square feet at most of tables, chairs, and window seats are attended to, but the larger part remains, to cast its accumulation into the air by the stirring of the beds and the tread of attendants and visitors upon the floors.

I need not detain you with a detailed description of the current methods of ward and corridor cleaning in hospitals. But in fact the one procedure by which the most satisfactory removal of dust may be secured is not practised. I refer to the use of moist

mops on the floors, and moist dust cloths on the solid furniture, and the careful removal and shaking out-of-doors of the night counterpanes, *all in the early morning before the stir of the day begins.*

Sweeping, if this be necessary, should be done before the quiet of the night is established. Then during the relative stillness of the night hours practically all dust and all floating infectious stuff will fall to the beds and floors and horizontal surface of the furniture, whence it may readily be removed. Thus once in the twenty-four hours a hospital may be largely freed from its irritating and infectious air-borne contaminations.

In speaking of the dusting of floors by a mop, I do not mean the usual mopping with the abundant use of water which leaves the floor more or less wet. I mean the use of a large mop, thoroughly wrung out so as to be only moist, not dripping, which is to be passed rapidly over the floor, touching but not lingering upon each part. In this way, as fast as the operator may walk, the whole floor surface is covered and a large area may be effectively cleaned of its dust before it is necessary to rinse and wring out the mop anew.

Of course the initiation of this procedure involves some slight change in the hospital cleaning routine commonly in vogue, which is largely directed toward the removal of visible dirt. But after all, the only essential change is in the moist dust removal, as indicated, in the early morning before it has been in any way disturbed.

Of course it will be said that this procedure is impracticable, that it is expensive, that it is useless, that it is based on finical, theoretical postulates, and savors of the laboratory. However, it has been the writer's good fortune to secure the cooperation of the administration in two large hospitals and in one large educational institution, in having the wards and public assembly rooms properly swept at night, while in the early morning before the wards were astir or the assembly rooms occupied, the settled dust was all removed in the manner indicated and safely sent to sea by the sewer.

In each instance, after the reluctance of the housekeeper to listen to the vagaries of sanitation had been overcome, the results have been most striking and satisfactory; nor has the expense of the change of routine been noteworthy.

In fact, it is much cheaper to get rid of the dust day by day than to keep it stirring, trusting to the chances of the hour that some of it will blow out of the window, or relying upon the friendly offices of the mucous membranes alike of the well and the sick.

In most modern hospitals much more money is wasted in overheating the wards and in blowing prodigious volumes of air out of opened windows in futile directions, that would be required to remove the dust in the most effective fashion. But this does require conviction, persistence, and unceasing supervision.

The tendency of modern medical practice to look at the sick man rather as a halting or disabled machine than as a diagnostic abstract to be dosed, as was so long the vogue, should, I think, lead the practitioner at least to a sympathetic attitude toward the efforts of modern hygiene to maintain an intelligent cleanliness of the air.

In all the delicate mechanism by which the healthy individual may, at need, protect himself against the ill effects of dust and infectious microorganisms, inspired in the air he breathes, the sick man is usually sorely handicapped. To put upon him the necessity of overwork by either his mucous membranes, his lymph nodes, or his phagocytes, or all of these together, is surely not more commendable than it would be to stuff with indigestibles a digestive apparatus of supreme importance in the emergency of illness, or in need of rest.

In view of the increase in respiratory diseases in cities, it is interesting to note that while water supplies are now at last usually subject to the most careful supervision on the part of municipal health authorities, while in well regulated towns food supplies are looked after with more or less intelligence and zeal, one of the three great necessities of human life, the air, which we are ceaselessly taking into the most delicate of our organs, is left almost wholly unguarded either by public supervision or private attention against wilful or careless pollution by the filthy, the vulgar, and the diseased.

While we are concerned in this paper especially with the accumulations of dust indoors where if proper methods of cleaning be not practised it is stirred again and again into the air we breathe, there are certain conditions out-of-doors in New York which deserve at least a brief mention.

An examination of the sanitary conditions in the subway is now being made by Dr. Soper for the Rapid Transit Commission, the result of which we may wisely await. Already many most interesting and significant facts have been brought to light. It is to be hoped that the Commission will realize the far-reaching importance of this research and see that it is carried to completion, so that we may definitely know in the future what to do and what not to do in the construction and administration of these important avenues of transportation.

But the stairways and platforms of the elevated railway have now, for many years, been swept with gross disregard of the welfare of its patrons, who are forced to breathe clouds of the most filthy dust when the attendants are sweeping. No public protest seems to be of avail with those responsible for this abomination. When the porters of the system feel like sprinkling the floor and stairs before sweeping, they do so; when they see fit, they omit it. Individual protest to the company meets with courteous response and the dry sweeping goes on just the same. The Department of Health has long been aware of this nuisance and danger. It has the power to stop it, but does not do so.

There was a time in New York when the street sweepers were required to sprinkle the pavement in advance of their brooms. But of late we are forced to lend to the Street Cleaning Department the good offices of our respiratory mucous membranes already overtaxed by the requirements of the theatre man, the storekeeper, and the trolley car folks, by the traditions of domestic service, and by the house committees of our clubs.

If, in New York, the beneficent law against the smoke pollution of the air were enforced; if the streets were properly cleaned; if the great passenger transport systems were placed under competent sanitary supervision; if the Health Department were persistently alert in enforcing the ordinance of the sanitary code which relates to spitting in public places; and if we could get sweeping and dusting indoors intelligently done, we should have in this city, in my opinion, a fair outlook towards a great advance in the reduction of diseases of the respiratory organs. These are indeed large and difficult "ifs" and they do not appeal as strongly to the public as does the search for a new "serum," but the demand which they imply seems not unreasonable.

The condition which we face is in short this: The infectious diseases of the respiratory organs are steadily increasing as people are more and more huddled together in offices, dwellings, traveling con-

veyances, and places of public assemblage. A large part of these diseases are directly traceable to infectious material cast off, in spitting, coughing, and sneezing, from the mucous membranes of those suffering from various grades of local disease, and floating for longer or shorter periods in the air as dust or invisible spray.

Promiscuous spitting can and should be stopped. Coughing and sneezing cannot be prevented, but in most instances their harmfulness can be controlled by the use of the handkerchief, or, in case of need, by such use of the hand as shall answer the dictates of primitive decency. This is a matter of public education. But when all is said and done in these directions there remain the humble offices of cleaning which can only be effective when conducted with trained intelligence.

The private citizen can stay away from the theatre and the opera, and this, if largely practised, would prove a powerful educational influence upon some of the worst offenders against the salubrity of the air. He may or may not be able to control his own office and workshop, but he can make the attempt. As for his home, he is lord of the castle—sometimes—and he may have clean air in abundance at the cost of a little vigilance and common sense; but he may, if he choose, and he usually does, contaminate his air with the floating refuse of the street and the wear and tear of his person and belongings, and breathe it so—*chacun à son goût*.

But as regards public conveyances and places of public assemblage, I see no reason why health authorities should not as properly prescribe regulations for cleaning and the removal of dust, and compel their practice, as they compel the sanitary disposal of sewage, secure pure drinking water, and condemn noxious articles of food.

WHAT CONSTITUTES PNEUMONIA.*

By ANDREW H. SMITH, M.D.,

NEW YORK.

Allow me to suggest a concept of an average case of pneumonia.

1. Granted that the patient, to begin with, is one of the multitude of who have pneumococci on the mucous surface of the air-tubes where the conditions being unfavorable for growth, they are harmless;

2. Granted that at some point nature's provision for keeping foreign particles, including pneumococci, out of the air cells fails;

3. Granted, that perhaps only a single pneumococcus finds its way to the *pavement* epithelium that lines the infundibula and the air-cells, where the conditions for growth are every way favorable;

4. Granted, that from some cause, local or general, the vital resistance has been lowered;

These four postulates being granted, the succession of events will be as follows:

Where the coccus rests in contact with squamous epithelium a peculiar specific irritation will be set up in response to which a peculiar fibrinous exudation will take place into the air-cell. This exudate will constitute a culture-medium exactly fitted for the growth of the parasite which will immediately begin its multiplication and the formation of its appropriate toxin. This toxin being taken up into the blood will produce systemic effects in proportion to its amount and virulence. The exuded material constantly increasing in amount, will overflow into adjacent cells and adjacent lobules, carrying the infection with it, until a sufficient area is involved to give rise to appreciable physical signs. The advent of these signs will be earlier in proportion as the observer is a competent auscultator, and is thorough in his examinations. The proportion of toxin in the exudate will increase until the latter becomes so poisoned as to be unfit to act longer as a culture medium, when the further growth of the parasite in that immediate locality will cease.

Meanwhile the pressure of the exudate, aided by the coagulating effect of the toxin will have brought about arrest of circulation in the capillaries derived from the *pulmonary artery*, and the *function* of the part will be completely suspended. The nutrition of the tissues, however, will continue to be provided for by the *nutrient* capillaries derived from the *bronchial* arteries and having the greater power of the left ventricle behind them, and thus gangrene will be averted.

So long as fresh areas of lung are being invaded so long will the systemic disturbance continue; but when the formation of toxin in the zone last to be invaded has ceased there will be a cessation of the general toxic phenomena, and a fall of temperature marking the crisis will take place. There is evidence going to prove that the crisis is hastened by the formation of an antitoxin in the infected tissue as a secondary process. So soon as the active process in a given area has ceased a process of repair is set up in which the nutrient vessels and the absorbents are the principal agents. As the result of this process the exudate is liquefied and is removed, partly by expectoration, but mostly by absorption. As this is accomplished the circulation through the functional vessels is resumed, and the part is restored to its normal condition.

The local conditions in developed pneumonia are such that gangrene would be inevitable in every case were it not that the *nutrition* of the lung is maintained by a circulation distinct from that by which the *function* is carried on. While the capillaries derived from the pulmonary arteries are completely occluded for many days in the affected part, those from the bronchial arteries are scarcely implicated and the nutrition remains intact. The significance in pneumonia of this double circulation was overlooked until the writer drew attention to it in the early nineties, and even now is very generally ignored.

So, too, is the difference overlooked between the columnar epithelium of the tubes and the pavement epithelium of the air-cells in relation to the growth of the pneumococcus, though a factor of transcendent importance in the concept of pneumonia, since it makes it clear how it is possible to have pneumonia ever present potentially, and yet continue to escape it actually.

As to what constitutes pneumonia, I contend that a single pneumococcus lodged in an air-cell and causing there its specific irritation and consequent exudation, presents all the essentials of the disease. It matters not if, ten minutes later, the organism is dislodged and swept away by the exudate, the patient even then has had a pneumonia, if only a *monococcal* one. Or, if later the bronchiole terminating in the lobule invaded becomes blocked, and the further spread of the infection is prevented, the patient may escape with a *unilobular* pneumonia, but he will have had a pneumonia all the same. Indeed, I strongly suspect that such abortive attacks are very common.

But what then becomes of the notion that the disease is at first *general*, becoming afterward *localized* in the lung? As if an infecting principle settled

*A five-minute paper read before the Medical Association of the Greater City of New York, December 11, 1905.

down upon the victim, from somewhere, perhaps from the clouds, and, after rioting about for a while, in the system at large, at last selected the lung as a convenient habitat. And this because the *general symptoms* commonly precede the *local signs;* which is like contending that the fire is an after-effect of the smoke because we commonly see the smoke first.

Has it never occurred to these brethren that the fever thermometer is a more sensitive instrument than the stethoscope?

If any one take exception to this criticism, let him point out in the average pneumonia the *extra-pulmonary* source from which the system is infected while as yet the lung remains free.

18 East Forty-sixth Street.

DANGER AND PROTECTION IN *X*-RAY WORK.*

By W. LEHMANN, M.D.,
SAN FRANCISCO.

Considering the many publications dealing with the dangerous effects of the Roentgen rays and the ways of avoiding them, and regarding the fact that already in textbooks, as for instance in Allen's excellent monograph, various devices have been given for protecting operator as well as patient, it seems almost superfluous to take the matter up again, but recent experiences have led me to review the subject.

When the Roentgen rays first were discovered it was necessary to make long exposures in order to get good pictures of the parts examined. Following these long exposures to which the patients were subjected, undesirable effects have been observed quite frequently. Burns, falling hair, atrophy of the skin, etc., were common occurrences. Soon the power of the apparatus was increased, and such a bright light from the *x*-ray tube could be obtained that the exposures which lasted for minutes in the beginning could be cut down to as many seconds, as early as 1896. The physiological effect of the rays upon the skin shown by the observed ill effects was then used to influence diseases of the skin. Thus use of the rays was made indiscriminately and again unexpected results reported. Only the wider and wider knowledge of the different qualities of tubes of lower and higher vacuum, of brighter and weaker light, enabled us to estimate the physiological as well as chemical effect of a given tube. Practical devices, as Holzknecht's chromoradiometer and others made it possible to give a certain therapeutic dose with an exactness approaching the well-known minimum and maximum dose of drugs. Our patients could be subjected to the rays for diagnostic examinations as well as therapeutic procedures in a comparatively safe way. Very few bad effects in patients have been reported lately. With experience we have mastered the difficult subject and are able to give the benefit of the rays to our patients without violating the first medical law: *nil nocere.*

But not yet have we overcome all difficulties of this work. Physicians themselves have experienced here and there the insidious effect of the new power upon their body. Every time the physician gave his patient a dose of his medicine he took it himself, taking a teaspoonful each time while the patient got a tablespoonful. These small doses had not the prompt effect of the large ones, showing results only with time and accumulation, so that years were necessary for all the dangers to the operators to be found and traced to their source.

The question of protection of the operator has become an important one, especially during recent years, when not only changes in the skin but the affection of vital organs have been reported as due to the ray.

Using their hands as a means to control the vacuum of the tube, a large number of operators have complained of a chronic eczematous condition of the skin, which became swollen, dry, boardlike, thickly skaling and cracking; ulcerations and sometimes unrelievable pains followed. The nails became dry, brittle, fissured and distorted, fell out, and were often permanently lost; the owner of such a hand was not only unable to do surgical work or disinfect the hand, but had in most instances to complain of severe pains beside the ugly appearance. We have too many examples of unlucky operators right here in town to necessitate a review of the existing literature. Repeated exposures often led to falling hair and permanent alopecia, and atrophy of the skin sometimes with a scleroderma-like appearance followed; the development of more or less extended teleangiectases did not only make conditions worse but soon proved to be incurable and not yielding to any therapeutic attempt whatever. Thus the soil was prepared for all kinds of infections, for painful and permanent ulcerations which in some instances finally became malignant, and cases have been reported in which amputation of fingers or even the whole hand has been considered necessary. It is not only in pathological ground that epitheliomata has developed—Mendes da Costa has reported seven cases of epithelioma in 71 cases of lupus treated with the rays—but an originally healthy skin, changed only by the Roentgen eczema, has degenerated into carcinomatous growth with sometimes a very rapid malignant course and leading to death in several instances. The ill fate of the Roentgen operator witnessed here in town is still vivid in our memory,* increasing the number of similar instances of which two years ago Allen reported four in his book. Since then about half a dozen more have been published.

Besides the local effects, general disturbances are not uncommon. Seguy and Quenisset have reported that continued work with the Roentgen rays caused peculiar cardiac palpitation with general uneasiness, followed by arrythmia. Probably everybody who operates Roentgen apparatus has observed accelerated action of the heart after prolonged exposures. Dr. C. M. Cooper called our attention to arteriosclerotic changes a few months ago. Likewise the extreme nervousness of some *x*-ray operators is probably due to the ray. Butcher is inclined to accuse the action of the ionized air in the *x*-ray room, an action which as yet is not determined but perhaps later will be considered as more important. On the other hand, we run across symptoms of the brain which are decidedly due to the Roentgen-rays. Dizziness, vertigo, headache, or a disagreeable full feeling of the head, and nausea have been observed. Walsh reported cerebral symptoms, closely resembling sunstroke. I do not think that this question has yet been settled; we probably will witness more serious disturbances with time. The peculiar affinity of the Roentgen rays to lecithin, which forms a large percentage of the chemical substances of the brain tissue, forces us to follow up the subject. Werner among others proved experimentally that lecithin exposed to the rays showed chemical disassociation, the products of which, like cholin, create, after injection into the body, symptoms very similar to the ones produced by the *x*-rays themselves. Gastrointestinal troubles can be found also in the

*Read before the San Francisco City and County Medical Society November 15, 1905.

*Mrs. A., who died of internal metastases of a carcinomatous growth which had developed on the soil of a "Roentgen-hand."

literature. Although in many instances not with certainty traceable to the rays, they are worth consideration in view of the publications of Oudin, Barthelemy, and Darier. Walsh reports the case of an *x*-ray worker, who gave his abdomen repeated exposures of long duration. After some weeks he complained of abdominal symptoms, pain, tenderness, flatulency, and diarrhea. While in the country these symptoms disappeared, but returned upon renewing the work. He got rid of them finally by protecting his abdomen with sheet lead. It seems the place here to mention Heller and Linser's experiments on rabbits which, after prolonged exposures, showed beside other changes, all symptoms of grave nephritis.

By far more important are the changes found in the genital organs, changes which lately have aroused the interest of the medical world and have frightened some Roentgen operators greatly. Already in 1903 Albers, Schoenberg, and Frieben published the results of experiments with animals. They kept rabbits in the *x*-ray room for several months several yards away from the tube and were surprised to see that these animals did not produce new generations, a fact which was found to be due to necrospermia, azoospermia, and even atrophy of the testicles. Buschke and Schmidt confirmed these findings and Halberstaedter in his experiments obtained the same results, apparently more quickly reached, in ovaries. Foveau observed cessation of menses following atrophy of the ovaries in thirty cases of fibromyoma of the uterus treated with the rays. The explanation of these facts, occurring without the slightest change in the integument, without burning or dermatitis of the skin, was easily given by the strong, almost specific affinity of the Roentgen rays for young, growing, constantly regenerating epithelial cells. These reasons, originally stated by Scholtz, had been supported by Heinecke, who found experimentally a destruction of lymphoid tissue, medullary cells and glandular substance, before other parts were affected.

By and by similar results came to the light in men: the treatment of pruritus ani was followed by the inability to generate and atrophy of the testicles. Philip dared to use this remarkable property of the rays therapeutically, sterilizing phthisical individuals. The proof of these astonishing and important facts was given by Brown and Osgood in the *American Journal of Surgery* in a paper which communicated the thorough investigation of the authors in an *x*-ray tube factory: eighteen workingmen, of strong good health and from twenty-two to forty years of age, were found completely azoospermotic. None of these had had a disease of the genital organs. None had functional disturbances or abnormalities. Men employed for more than three years had no spermatozoæ at all, others showed necrospermia and oligospermia alternately. Half of them were married and had no children since handling *x*-ray tubes.

It seems to me these facts are not only surprising but frightening. If somebody were to try to make inquiries of all men who have handled or are handling the rays, alarming results would be obtained. Not only among the early operators in this field who were ignorant of the dangers connected with the rays, but also among younger men who take up the work without proper knowledge and care, facts could be revealed which would not only deter them from further exposing vital organs and essential faculties, but would discredit the entire use of the Roentgen rays.

This is not the place to enter into a discussion over the theoretical ways in which the rays act. But it seems necessary to touch upon the experiments of Baermann, Linser, and Helber which convinced the authors that the primary changes produced are those in the endothelial cells of superficial blood-vessels, followed by the destruction of blood cells and the formation of certain toxins, which would be apt to transport the action and produce effects on parts of the body far distant from the parts treated. Fortunately these experiments are not quite conclusive—otherwise all our devices of protection would be useless if they leave the possibility of the rays reaching indirectly well guarded parts of the body. In this line an autopsy recently performed by Dr. Ophuels resulted in some surprises, revealing complete atrophy of both testicles, both seminal vesicles, and the prostate in a man who had been treated for months and months, and whose genital organs had always been carefully protected from the direct access of the rays. However, the man had an old gonorrhea and splenomyelogenous leukemia of the worst kind, both facts which would account for the findings. Furthermore, leukemic enlargement of neck glands which had appeared several months before had disappeared under continued treatment without being directly exposed. Still an explanation may be possible by the effect of the so-called "secondary rays."

As the cathode rays transform their energy into Roentgen rays by striking the target, so the Roentgen rays produce secondary rays by striking the glass wall of the tube, striking the air between tube and patient, and striking the tissues of the body itself. To be brief, this much may be said about the secondary rays, discovered by Walter, that they are very similar in action to the Roentgen rays, more highly penetrating, less effective physiologically and chemically, and produced more profusely by high penetrating *x*-rays than by rays sent out from a soft tube. As the secondary rays move from the point of origin in straight lines in all directions, it is evident that they are able to reach a point which is shielded from the directly impinging *x*-rays.

Thus we have to shield the operator from secondary rays as well as the *x*-rays. For examining the vacuum of the tube we never use our own hand, we provide ourselves with one of the many radiometers like those of Walter, Benoist, Biesalski, or better, follow the device of Kohl's artificial hand, brought into a convenient form in Beck's osteoscope or Schmidt's cryptoscope. The latter is a fluoroscope, before the screen of which a bony hand enveloped in thin tinfoil (representing the fleshy parts) is mounted. The hand using the apparatus is protected by a lead shield surrounding the handle, the eyes, and the face by a lead glass plate covering the barium platinocyanide screen.

Obviously the operator will stand as far from the dangerous tube as possible, always behind the plane of the anode and above the level of it: the latter can be carried out especially well with the tube placed very low and the operator on a floor several feet higher. In the best tube, however, there are aberrant cathode rays, apt to produce Roentgen rays at any point of the tube, so that above as well as behind the "*x*-ray field" still a considerable amount of dangerous light exists as fluorescent screen and photographic plate will reveal. Therefore a number of operators advise the use of a tube box made of or covered with an impermeable metal, preferably lead, a box which opens only on the under surface with a small hole, allowing exit to the rays. Although the holes for the lead wires and other avenues of escape for the rays, the heavy weight, and the difficult handling of the heavy apparatus were objections to it, it was practically safe. But only very low tubes al-

lowed the use of the box, as otherwise the high-tension current very frequently jumped from the electrodes of the tube to the surrounding metal. The most serious objection, however, which should suffice to abandon all devices of the kind is the impossibility of controlling the vacuum of the tube, of observing the changes in the brightness and penetrability of the light; without a permanent control of that we lose sight of all consequences which may follow a given treatment, and we are unable to estimate the result of a diagnostical exposure. Better was the idea of making this box or the tube itself of lead glass. Only a small round part of the glass wall, opposite the target, was of thin glass allowing exit to the rays. Tubes of this design are on the market, but of very small size and unable to stand the large current of a modern coil. When these lead glass bulbs can be made of the large size and the same design as our modern water cooling tubes, for instance, are, we will have the ideal apparatus for safe work. Half bulbs of lead glass to be attached to the tube and absorbing all the rays which leave the tube through its under half (besides a small opening provided for) are practical, but so heavy that they must be fixed to the tube stand in a special way with the tube resting on them.

The main protection for the operator is a heavy lead-covered screen between the tube and his body, and the possibility of handling the apparatus and appendages from behind. This screen made of wood and covered with lead one-sixteenth of an inch thick consists of two parts each, six by three feet, connected by hinges, and running on wheels, so that it can be moved with ease and brought to any position wanted to shield the operator. The crack between the two parts is also carefully protected with sheet lead, the screen provided with a small lead glass window which allows the physician to observe tube and patient and which although practically impermeable can even be closed by a lead shutter. If this screen, which in Albers-Schoenberg's laboratory is enclosed on four sides forming an unradiable closet, is to be of real benefit, the operator should be enabled to set in action and control every apparatus in the room from behind. A switch table or a wall plate provided with as many connections as necessary will answer the purpose. The switch table in the Roentgen Department of Cooper Medical College (furnished by Hirschmann, Berlin) allows the regulation of the strength of the primary current and the change of the poles, the connection with the coil with or without condensor, the connection with the motor interrupter (providing a rheostat for the regulation of the speed of the motor), with each of three different platinum electrodes of a Wehnelt interrupter outside of the room, and finally a variable connection with the four primary layers of the coil thus permitting changes in the self-inductance of it. The strings of the series of spark gaps as well as a balanced string working the regulation attachment of the tube can easily be fixed so that they run along the ceiling and end in handles which will be found behind the screen in easy reach of the operator's hand.

Thus practically all the work beginning with starting the primary current and ending with the regulation of the vacuum of the tube while in action can be done from behind the screen. I may be permitted to add that all these arrangements are only possible with a coil. A static machine cannot be handled from a distance; another and the most important reason against the use of the static machine for *x*-ray work, besides other disadvantages which have been alluded to in other places.

The use of a large mirror placed on the wall opposite the tube, and in plain view of the operator, will enable him to control the tube without a window in the screen, or the window in the lead-protected closet is not directed towards the tube but toward the mirror, allowing the observation of the reflected image of the tube.

After having placed in position patient and tube, we go behind the screen and give treatments, or make diagnostic exposures without the slightest injury to our own body. However, beside plates to be made and treatments to be given we are frequently called to make examinations with the screen. As far as the extremities, joints and head, bony diseases, or fractures and dislocations are concerned we refuse to do the work. In all cases of this kind the film of the plate will give a clearer evidence of disease or of small splinters accompanying a fracture, than the diffused image on the screen. A few seconds are sufficient to make a plate, while examination will abuse our expensive tube for several minutes. Only in cases in which the Roentgenoscopy will furnish more and better details than a plate, cases in which the motion of internal organs has to be observed in order to clear up the diagnosis, will we expose ourselves for the sake of the patient. The ortho-Roentgenoscopy of the heart, the observation of William's sign in early tuberculosis of the lungs, of the differences of transparency of different parts of the lungs in in- and expiration, of the motion of the diaphragm and its change in abdominal diseases, etc., etc., will oblige us to leave our screen. As the fluoroscope is merely a plaything for exact examination, replaced long ago by the single screen used in the easily darkened room, we have no use for the mirror or reflecting fluoroscope advised by Johnston. In this apparatus the shadow cast on the screen is reflected by a mirror the image of which only can reach the observer's eye. Small protective screens with movable openings which partially shield the operator but interfere with the case of examination, are still better. Most certainly the best ways of protection are gowns of impermeable material. Complete suits, caps, aprons, sleeves, gloves, etc., have been made of material of different degrees of safety. The better they fit and the more the examination is facilitated the less useful is generally the material. The safer the outfit the heavier and bulkier it is. Sheetlead of considerable thickness alone is really safe, and it is evident that all devices made of that heavy material must be bulky and rather inconvenient. The protectives I am able to show you to-night * seem to solve the question pretty well—the heavy apron reaching from the neck to the knees is Roentgen-ray proof and is, in spite of its weight, without inconvenience; the cap made of the same lead-containing material covers face and head on all sides and is provided with lead glasses. The gloves are likewise light proof and still neat enough to permit the handling of screen and apparatus. Practically safe, the operator will prefer this secure feeling to the inconvenience which never lasts more than a few minutes. The general practitioner who uses his apparatus but rarely can hardly equip his office with all the devices of protection referred to; but every man who works with the rays more or less constantly should never neglect the possibility of serious results caused by the insidious properties of this as yet not entirely known medium.

TRACHOMA IN CHILDREN.*

By C. COLE BRADLEY, M.D.,

NEW YORK.

OPHTHALMOLOGIST TO THE NEW YORK CATHOLIC PROTECTORY, TO ST. JOSEPH'S ASYLUM, TO ST. JOSEPH'S INSTITUTE, AND TO THE HOME FOR INCURABLES.

TRACHOMA in the children of New York City and particularly in the school children, has occupied a prominent position in the public eye during the past two years, and has at last been recognized by the Board of Health as a decided enemy to be fought as strenuously as the other contagious diseases of childhood.

Two years age there was great ado in the public press over the epidemic of trachoma in the public schools. The disease was not truly epidemic, but for the first time it had been brought forcibly home to the Health Board by Dr. Richard H. Derby, the consulting ophthalmologist, that the disease existed in a large and increasing proportion in the school children. This large proportion was simply the natural increase of an insidious contagion, that had either not been discovered in the school children or had not been considered sufficiently dangerous in its effects to necessitate drastic measures.

It will be remembered that in 1886, after an examination of the inmates of asylums and public institutions for children of New York City, by a committee of ophthalmologists, Fellows of the Academy of Medicine, the legislature passed a law entitled "An Act for the better preservation of the health of children in institutions." This law required that the eyes of the children should be examined on entrance, and that cases showing contagious disease should be isolated. It also provided for a monthly examination of the eyes of all the children.

The caustic criticisms of the committee, on the care given to the condition of the eyes of the children in the institutions, and the enactment of this law by the legislature was productive of great and positive improvement in the condition of the institutions and their inmates, during the ten years following. This was ably shown in a paper by Dr. Derby, read before members of the Academy of Medicine about two years ago. It was then forcibly brought out that while the inmates of the public institutions were well taken care of, 60 per cent. of the cases entering the institutions came direct from the public schools, where no recognizance of the disease was taken. It is now a matter of history how ably the Board of Health met the situation. Hospitals were established for the treatment, operative and local, of the afflicted children, and a careful system of regular inspection by competent inspectors was formulated. Children showing the disease in an actively contagious form were excluded from school until cured, and milder cases were required to show evidence of regular medicinal treatment.

At the first inspection of the school children, as reported in a paper by Dr. Lambert, in January, 1903, 7,571 children out of 55,000 examined showed different grades of trachoma, or 13 per cent. This seemed a great proportion and it is interesting to compare the statistics compiled by other observers relative to the frequency in other countries. Boldt writes of the examination in Königsberg of 17,553 school children. Of these, 5,847 showed trachoma, or 31.3 per cent. After two years an examination showed but 538 children afflicted, and still later a reduction to 393 (2.2 per cent.). In 1880 in an examination by Dr. Jitta of the school children of Amsterdam, 35.5 per cent. exhibited the disease. In 1897, 16.7 per cent., and in 1901, 7.8 per cent. Dr. Edward Jackson, in the ophthalmic year book, gives the stitistics prepared by Eloui-Bey relative to the frequency of trachoma in the school children of Cairo. In 1898, in schools of the poorer class, 96 per cent. showed the disease. In three years the percentage fell to 85 per cent. In the government schools of Cairo the percentage of cases has diminished from 85 per cent. in 1884 to 34 per cent. in 1900.

Comparing these statistics it will be seen that New York even two years ago was not in such a hopeless condition, and we are sure the percentage of cases must have been greatly reduced during the past two years. It is interesting to note how the treatment by the Board of Health of the school children has lessened the proportion of afflicted children entering the institutions for children. At the New York Catholic Protectory the percentages in the male department, as compared with those of former years, are as follows: 1900, trachoma, 19.5 per cent; 1901, 14.9 per cent.; 1902, 15.9 per cent.; 1903, 11.3 per cent.; 1904, 9.2 per cent. In five years a reduction of one-half is shown, and other institutions that receive children of the school age where exclusion cannot be practised, must show a like reduction. It is seen, therefore, that while the crusade against trachoma by the Board of Health has been of the greatest and most lasting service to the school child, it has also been of great benefit to the unfortunate wards of our great city institutions.

The disease may be defined as an inflammation of the conjunctiva due to a specific organism characterized by a development of hypertrophied areas and followed by the formation of cicatricial tissue with its consequent contraction. There is little doubt that it is caused by a specific organism, which has yet to be demonstrated. Koch, while in Egypt, found in the conjunctival discharge, gonococcus and what is known as the Koch-Weeks bacillus. Neither of these, however, are regarded as the specific organism of trachoma. Dr. L. Mueller describes as a cause of the disease a bacillus with rounded ends, the colonies of which show glassy structureless edges, even with a magnification of eighty diameters (Jackson). The

*Read before the Medical Association of the Greater City of New York, May 8, 1905

disease is spread by being carried directly from one person to another. In school, the double desk, the loaning of pads and pencils, the occasional roller towel, etc., are familiar methods of extension. It is not believed that infection takes place through the air as a carrier. Stephenson particularly speaks of the immunity of teachers and nurses in the Hanwell Ophthalmic schools, and says that out of sixty-five nurses and sixteen teachers none were infected during a five years' service. Trachoma is not equally infectious at all times and under all circumstances. Its infectious quality varies with the amount of secretion. Usually both eyes are affected, though occasionally one finds a unilateral trachoma. As a rule the second eye is later attacked, as has been shown fairly conclusively by Raehlmann.

In this city the male sex is more subject to the disease than the female. In some of the schools which I examined the percentages shown, were, in the boys 13 per cent. and 12.7 per cent. while in the girls it was 1 per cent. and 2.9 per cent. In the New York Catholic Protectory the cases in the male department exceed those in the female by 13 per cent.

We meet with the disease in the two forms, acute and chronic. At first there are often no symptoms other than slight discharge in the morning, the presence of the disease being discovered accidentally. In other cases there is lacrymation, burning and itching of the lids, and sometimes sensitiveness to light. In acute form the symptoms are very similar to those of a purulent ophthalmia. The lids are red, swollen, and edematous, while the palpebral conjunctiva is greatly thickened. The ocular conjunctiva is also injected and swollen, sometimes showing decided chemosis. This is rarely sufficient in extent to endanger the nutrition of the cornea, as in purulent ophthalmia, though one does meet with corneal ulcerations occasionally. Often in the early stage of an acute trachoma one can see the characteristic granules in the conjunctiva, while later, when the acute symptoms have subsided, they can be easily demonstrated, particularly in the culs-de-sac. There they appear as opaque granules beneath the surface of the conjunctiva, sometimes discrete and prominent (the papillary form of Fuchs) and at other times forming confluent masses of a gelatinous appearance (the so-called gelatinous trachoma of Stellwag). The appearance is then one of subacute trachoma.

Later, if unchecked, there is contraction of the palpebral slit, due to the thickening of the upper lids, followed by the slow formation of cicatricial tissue with its consequent contraction. Often accompanying this condition is seen the vascularization of the cornea (pannus), with its diminution or possible destruction of vision. Iritis occasionally occurs, while entropion, trichiasis, and xerosis of the conjunctiva may follow in severe cases.

The form seen daily in the children of New York is the soft follicular trachoma, and here appears the difficulty of diagnosing between follicular conjunctivitis and trachoma. Some have claimed that the school children were suffering from an epidemic of follicular conjunctivitis rather than from trachoma, and have intimated that the strenuous efforts of the Health Board were rather far-fetched and possibly unnecessary. Fuchs gives rather an elaborate description of both diseases, but ends by saying "that they are often distinguishable only by their course." It has been my rule to classify as follicular conjunctivitis those cases in which the follicles were limited to the lower lids. In these cases they are lightly scattered over the lids in rows and are superficial. When, however, these same benign follicles appear on the upper lids, even without deep infiltration of the conjunctival tissue, the case should be classed as trachoma. Cases that respond to mild astringents in a short time, or to fresh air, better food, and to relief from errors of refraction are cases of follicular conjunctivitis. Where there is a doubt, it is safer to separate and isolate, as has very properly been done by the Health Board. Later, the hypertrophy and consequent shrinking of the conjunctiva will surely appear if it is a true case. The pathogenic microbe alone will furnish us with the elements for a scientific and positive diagnosis.

The course of the disease is very slow, and even under the best treatment will last for months. The treatment of the acute form which so closely resembles purulent ophthalmia, is practically the treatment of the latter disease until the acute stage has passed. Ice compresses, frequent flushings with solution of bichloride of mercury 1-6000 or with solution of formaldehyde 1-3000, and the use of solutions of silver salts every three hours are found of service. For the form other than the distinctly acute, treatment by the use of local astringents or by means of operation is practised. Of local astringents, glycerite of tannin, nitrate of silver, the newer silver salts, and sulphate of zinc have been found efficacious by some. I have found glycerite of tannin to be of little use. The old 2 per cent. of nitrate of silver solution is more effective than the newer silver salts which I have found to have but little effect on the trachomatous process itself, though they are useful in checking the excessive purulent discharge shown in some cases and particularly after operation.

The remedy, sulphate of copper, or blue stone, has been, and is, almost universally used in private practice and in the public clinics. I have not used a blue stone pencil for the past ten years. It has been our misfortune at the Protectory to be compelled to receive children from other institutions, notably from Randall's Island, where the blue stone treatment has been rigidly carried out. In these children and in others where long treatment with blue stone has been given, as in the public clinics, it has been very positively impressed upon me that the extreme cicatrization of the lids shown in these old chronic cases and ordinarily ascribed to the disease itself has possibly been in great part brought about by the long-continued application of the blue stone. The same amount of long-continued treatment with milder remedies such as nitrate of silver in 2 per cent. solution and the bichloride of mercury does not show this great cicatrization of lids. Dr. Sydney Stephenson believes that the long-continued use of the copper pencil is liable even to produce opacity of the cornea.

Of all remedies, I have found the use of bichloride of mercury the best. Keissing in 1890, and Darier several years ago, wrote of massaging the lids with 1-500 solution of bichloride of mercury, and very recently Dr. Parker of New York City in an article advocated its use in this way. For ten years I have used the bichloride of mercury solution 1-100 or 1 per cent. in the cases in which blue stone would ordinarily have been used. In these severe cases I have not found 1-500 solution strong enough. The application has been made every second day, and every part of the everted lids carefully touched. The after-effect in touching a case is to produce an eschar resembling that produced by application of silver nitrate. This is separated

by the second day, when the lid may be retouched. After two or three applications the lid does not show so much reaction. I have found that applications three times weekly, with flushings of the lids twice daily with a solution of bichloride 1-6000 gives the very best of results. When the case is not so severe, occasional touching with the bichloride solution 1 per cent. combined with the daily use of silver nitrate, gr. viii to the ounce and the bichloride flushings give excellent results.

Copper citrate in 5 per cent. ointment I have found of use in cases showing pannus. I have not as yet had sufficient experience with it to speak positively of its general efficiency. It is painless and can be given to the patient for home use. Dr. Emil Bock has written of the treatment of fifty-eight cases with copper citrate, with excellent results. He employs it twice daily in 5 per cent. and 10 per cent. ointments. There is very little reaction after its use. Van Arlt also advises its use two or three times daily, and prescribes it in the form of an ointment made with glycerine and starch. The operative methods are mainly scarification and brossage, the excision of the cul-de-sac, and expression. The first two I believe uncalled for, excepting in very special cases. I have never practised them. Expression, however, lessens the duration of the disease markedly, and also the tendency to hypertrophy with its consequent cicatricial contraction. I use the familiar expression forceps of Knapp with smooth or rough rollers, the ring forceps of Prince, which are used more as a fixation forceps for everting the lid and exposing the cul-de-sac, and a sharp curette.

In performing the operation over 600 times I have never found the use of a general anesthetic necessary. Cocaine in solution, even 20 per cent., I do not find induces sufficient anesthesia to perform a painless operation, as has been claimed by Dr. Bardes. It is necessary to use the powdered cocaine. I massage the powdered cocaine hydrochlorate into the exposed conjunctiva of the lids by means of a shell cataract spoon, two grains sufficing for both eyes. The eyes are closed for four minutes and a small quantity is again massaged in. In six more minutes the lids will stand the necessary amount of pressure. After the follicles are thoroughly emptied by expression I go over the surface of the lids with the sharp curette, removing the shreds of denuded membrane and picking out, after the method of Sattler, individual follicles that failed to rupture. After and during the operation the cornea is carefully cleansed of deposit, and the lids flushed with solution of formaldehyde 1-2000. Borated vaseline is then placed between the lids and a compress moistened with the formaldehyde solution is bandaged on. This is removed after six hours, and the eyes for the next three days are flushed frequently with formaldehyde solution 1-3000. After the third day silver nitrate 1 per cent. or some other silver solution is used daily if there is much discharge, and frequent flushings with 1-6000 bichloride of mercury solution are practised until the case is discharged. It is quite possible to discharge cases in which the follicles have been plentiful within two weeks, while under local treatment three to four months would be necessary to effect a cure. It has been claimed that the use of cocaine causes desquamation of the corneal epithelium. After the operation, the cornea will often be found steamy and sometimes quite opaque in appearance. A cotton tipped probe dipped in the formaldehyde solution will remove this gelatinous deposit, and the cornea will be found to have its normal luster. In the 600 cases operated upon I have never seen corneal ulcerations follow. The use of formaldehyde solution during and after the operation I find to be of greater service than the use of solution of bichloride of mercury. There is less reaction and much less discharge after its use.

Operations I believe to be admissible only in cases in which the granules are expressible. Where they are hard and inexpressible, the use of 1 per cent. solution of mercury bichloride gives the best service. Dr. Treacher Collins writes of the treatment of forty cases of trachoma by the *x*-ray at the White Oak School, Swanley, England. Exposures were made daily during the first week, and on alternate days during the second week. They were then discontinued for a time, until the amount and character of the resulting reaction became manifest. Some excellent results are recorded, notable in the severe chronic cases with pannus. Ruggio Pardo also claims excellent results with the *x*-ray.

Mayo has claimed cures by the high frequency current after twenty-two applications. He claims that the chief advantages of the treatment are, first, there is considerably less deformity in the lid after treatment; second, it is practically painless; and third, pannus clears more thoroughly. To summarize I wish to emphasize that,

First: The general use of sulphate of copper is not altogether harmless.

Second: The use of 1 per cent. solution of bichloride of mercury is harmless, and is equally good in its curative results as sulphate of copper.

Third: Copper citrate is apparently harmless, and is devoid of the objectionable features of copper sulphate.

Fourth: General anesthesia is unnecessary in the operation of expression. Cocaine hydrochlorate, in solid form, answers every requirement and obviates the necessity of a hurried operation, with its frequent extensive laceration of lid tissue.

616 Madison Avenue.

TWO CASES OF PSEUDOLEUKEMIC ANEMIA OF INFANCY.

By E. MATHER SILL, M.D.,

NEW YORK.

ATTENDING PHYSICIAN AT THE GOOD SAMARITAN HOSPITAL, CLINICAL ASSISTANT IN DISEASES OF CHILDREN AT CORNELL MEDICAL COLLEGE.

Von Jaksch in 1889-1890 was the first to describe this disease and give it this title. He based his diagnosis on the following points: That it is a disease of infancy, with marked oligocythemia, oligochromemia, permanent leucocytosis, marked splenic enlargement, moderate or slight enlargement of the liver, and at times enlarged lymph glands. Clinically it is differentiated from leukemia by the disproportion between the size of the liver and that of the spleen. In simple anemia the leucocytosis is not so great and the spleen is only slightly enlarged. According to Luzet this is a very rare disease and does not occur after the second year. He met with it only once in 1500 cases of anemia. He lays great stress on the presence of nucleated red blood cells.

Most of those who have written much on this subject claim that syphilis, rickets, malaria, and the digestive disturbances have nothing to do with the cause of it. Monti reports, however, more than three-fourths of his cases as showing evidences of rickets, and one patient had syphilis. The prognosis in the severe cases should always be most

guarded. All of Rotch's cases ended fatally, and 20 per cent. of the cases reported by Monti were fatal. One of my patients died in six weeks from the time I first saw him; the other is still alive after five months and is steadily improving.

My first case was that of a child ten and a half months of age. The father and mother well. It was breast fed for one month, then given one part of grocery milk to three parts of water until three months of age, when equal parts of milk and water were given. After the sixth month the child received three parts of condensed milk to one of water.

Twelve weeks before the child was presented at the clinic it was taken with diarrhea and vomiting, which has continued more or less persistently ever since. The child was now in a greatly emaciated condition, with distended abdomen and marked pallor; there was prolapse of the rectum. The child had an enterocolitis with ten to twelve watery stools a day containing mucus, blood, and curds. Vomiting was present also. On palpation the spleen was found to fill more than half the abdominal cavity and to extend well into the pelvis and to the right of the umbilicus. It was smooth and hard and notched on the right surface about the middle. The outline of its size is well shown in the illustration drawn from a photograph.

An examination of the blood was made by Dr. T. N. Hastings, of Cornell University Medical College, with the following findings: Hemoglobin, 30 per cent.; red cells, 4,064,000; color index, 0.35; white cells, 84,000.

Red Cells: Poikilocytosis, slight; polychromatophilia, marked; anisocytosis, marked; granular basophilia, slight. Nucleated red cells: Normoblasts, 39, megaloblasts, 4, malarial parasites not found.

White Cells: Differential (400 counted), polymorphonuclears 38.5 per cent., lymphocytes 44 per cent., large mononuclears and transitionals, 12 per cent., eosinophiles 2 per cent., mast cells 3.5 per cent., myelocytes 0.

The diarrhea was cured in this case and the child was given a modified milk suitable for its condition. It was put on the syrup of the iodide of iron and small doses of Fowler's solution, under which treatment there was a decided improvement; the spleen was reduced in size more than one-half in the course of six weeks; but then the child with no apparent exacerbation of symptoms, died.

My second case was in a child ten months of age, who had nursed for the first three months, and then it was given equal parts of milk and water. The child had had several attacks of diarrhea. For the past few months it had been getting bread and butter, farina, soup, and plain milk.

Examination showed marked pallor and a yellowish hue to the skin, malnutrition, beading of the ribs, enlarged and rigid abdomen. The spleen was enlarged four fingers below the free border of the ribs; the liver was slightly enlarged.

Blood examination by Dr. Hastings shows: Hemoglobin, 40 per cent., red cells, 3,800,000; color index, 0.53; white cells, 31,000.

Red Cells: Anisocytosis marked, macrocytes numerous, polychromatophilia marked, pallor marked. Nucleated red cells: four normoblasts found; malarial parasite not found.

White Cells: Differential (300 counted), polymorphonuclears 49 per cent., lymphocytes 42 per cent., large mononuclears 8 per cent., eosinophiles 0.5 per cent., mast cells 0.5 per cent., myelocytes 0.

This child is still alive five months after it was first seen by me, and is considerably improved. Its treatment has been proper diet, cod liver oil, and Fowler's solution. The *x*-ray has been used in this disease, with, it is said, marked benefit and some cures. I have had no personal experience with it, but that of others shows that it should be given a trial. Holding and Warren have collected twenty-two reported cases of pseudoleukemia treated by the *x*-ray; 27 per cent. being symptomatically cured, 59 per cent. improved, and 14 per cent. unimproved or fatal. Thus statistics seem to indicate that the *x*-ray should have the preference, or at least be used in connection with other modes of treatment.

It would seem, then, in these cases the disease was due to fatty feeding and gastrointestinal disturbance.

AIR DE LUXE.

By W. P. Northrup, M.D.,

New York.

The human animal seeks warmth. The Esquimaux returns from his long day on the ice to revel in his stifling hut. The dog and the cat curl up on the hearth and bake. In common with all animals, man eats when he is hungry and slakes his thirst as needed. It is only when the animal man reaches a high degree of civilization that he washes, purely to be clean. Not even yet does he take thought as to the air he breathes. Man does not thrive in overheating and lack of ventilation, neither do captive animals in like conditions. Healthful living in crowded surroundings demands intelligent regulation of heat and ventilation.

I congratulate the members of the New York Academy of Medicine that in the bright dawn of this much-mentioned twentieth century we can lay claim to being clean. We wash. We love, as good Americans, to throw back our shoulders, "chesty" fashion, and tell of the things we do. Sure enough, we eat, eat too much, sleep not enough, wash about right. Somewhere in coming decades we will wait for the later step: living in good air. Our rooms are practically bell jars. Doctors have not always thought of ventilation. When the reader of a paper sees his audience gently succumbing to a thickening atmosphere he need not take it to heart too much. It is only the Academy air. It is well that modern electric illumination does not dim and burn low in such. The human body, enveloped in hot, humid, used-up atmosphere, lives on, unapprehensive, stewing in his own juice; poisoning is over at eleven o'clock. The thin, dry man and his fat, perspiring neighbor sit down together in the bell jar, and amiably exchange exhalations, gases, and body emanations. They cough and sneeze into the swaying common investment, and severally inhale it again. Increasing mental hebetude leads gradually to nodding, torpor, and stupidity. Long experience teaches that close air is not quickly fatal. The cool, fresh air that is heaped up all about the building and cannot get in kindly bathes the

body on the homeward way, airs and restores the blood; so the incident closes and is forgotten.

Have we ever reflected how many hours a day our citizens live in bad air—overheated, moist, pent-up atmosphere? When New York wakes in the morning a majority shake themselves loose from the heavy air of an all-night entombment, emerge from unventilated rooms, engulf a lump mass of breakfast, and huddle into an elevated train. The ventilators are closed, and the bell jar again retains all body exhalations welling up about their heads. In the Subway the hurrying mass in rush hours are doubly heated, steaming, doubly enveloped in car and tunnel. The air is heavy, malodorous, moist. The human pack which sways and bowls about a trolley car has but little more ventilation, and the horse car, whose moribund slowness makes so little draft that even a man with a toothache could not object, is seldom ventilated. It hitches along the street, a covered tank of foul-smelling emanations, and yet, heaped high above it, crowding it at every side, at every crack and weather strip, is cool, oxygen-full air gently flowing about in the vain endeavor to get in.

The aforesaid majority hurry from close, overheated cars to counting room, back office, sweat shop or salesroom, bend over their work, sewing, typewriting, or counting till noon, and again till night, retrace the short space to the car, and swing from the straps to a late supper. Barely a half hour have they been, thus far, in out-door air.

There is one thing in New York that is all that can be desired, that is the combined open-air surface car. We do not relish the particular brand of tobacco which the laborer converts into pipe smoke and distributes from a forward seat; no more the ten-cent cigarettes (ten cents for twenty), nor yet the saliva-soaked dying butt of the perpetual smoker, but we can live and inhale the smoke, for there is a mechanism which selects our oxygen, maltreat it as we may.

I predict that the dawn of the twenty-first century will see New York houses ventilated. It is a long allowance—twenty centuries—but we seem to have needed it. It is within twenty years that forced ventilation has been installed in mines and Atlantic liners. The mechanical problem of ventilation has been solved for assembly rooms, lower decks, subcellars, tunnels. It is a mere matter of expense. Do we need further time for development and education? Twenty full centuries should be enough. We of our day drink and wash, next we will ventilate. We will see to it that the theater, the lecture hall, even the section rooms of the Academy, are ventilated. We will not be content to enter the bell jar with too many fat friends and swap breaths. There will be a demand for ventilation.

Steamheating, that iniquitous overdoing of a good thing, will be controllable. People must live in small rooms in this human hive, but the air can be changed often enough to carry away that which is used up. The time will come when people will refuse to breathe the effluvium from others' decomposing secretions, will refuse to draw deep into their vitals second-hand breaths.

The curse of living just now is overworking, overheating, lack of ventilation, not to mention worry and hasty eating.

By air de luxe I do not mean five-dollar canned air, made by the hired man. I mean another kind, delivered day and night without extra charge; one that does not smell of rubber nor dry the throat, that does not go to waste on the struggling nor annoy the dying. It is not one of those physical products controlled by syndicates, pooled by trusts, and cornered by kings. The poor throw it away, and the rich pick it up—in Switzerland. To disclose the secret, it is plein air (French spelling). It is not "made in Germany". It is *air to spare*.

I would counsel adding another floor to our houses, a roof garden. We buy our lots from bed rock to sky. Why not use the best part of them? There is a block, mountains high, of good air overhead. It is ours. With prodigal hand we roof it out, and distrusting our house atmosphere in sickness, buy canned air. When the patient fights against this, we wait until he is too sick to remonstrate, then we blow it into him.

Some time, when the gummy clay which clogs our feet has brought us to a standstill, some one will discover a new thought. Some brilliant intellect will point to our time, and laughingly jerk his thumb. "They ate, drank, and washed," he will say, "but they didn't think, and they didn't ventilate." We are indeed washers, not thinkers. We are getting perilously near the time limit. If the asphyxiating bell jar of our own devising does not finish us, let pass the euthanasia sponge.

57 East Seventy-ninth Street.

Spirillosis in Portuguese West Africa.—A. Yale Massey makes the following suggestions: That the term spirillum fever be used for the tropical cases, instead of relapsing fever, until the (?) various spirilloses are differentiated. That careful clinical notes be taken of each case where spirilla are found in the blood. That the biting insects of the locality be catalogued. That there be in each case a careful search for trypanosomes. He reports the case of a white Portuguese trader who was brought to the hospital in a very weak condition. He gradually sank into a semicomatose state, passing urine and feces involuntarily. The temperature of 103.4° F., dropped only at death, which occurred three days later. Examination of the fresh blood showed innumerable spirilla in a very active condition. They knocked the red blood corpuscles about most vigorously. This man had lived at a trading post several miles removed from any other white man. His associations and habits were native. The writer thinks that this disease has doubtless often been overlooked and put down as malignant malaria or blackwater fever, as the urine is very highly colored, although it is not the characteristic haemoglobinuric urine. That the disease is not very common, the writer believes may be explained by the fact of an acquired immunity. He suggests also that the disease may be carried by a large fly which more commonly attacks animals and only occasionally bites human beings.—*The Journal of Tropical Medicine.*

Word-Blindness with the Record of a Case Due to a Lesion in the Right Cerebral Hemisphere in a Right-Handed Man; with Some Discussion of the Treatment of Visual Aphasia.—Charles K. Mills and T. H. Weisenburg state that the two chief varieties of word-blindness usually described are known respectively as cortical word-blindness and pure word-blindness. As a rule in word-blindness the brain lesions are located in the left hemicerebrum. The only exceptions to this are supposed to be found in left-handed individuals. The writers report the interesting case of a patient 35 years old who had had a severe apoplectic stroke. The man was right-handed. When he recovered from the immediate effects of the attack he was found to be completely hemiplegic in the left side and almost absolutely aphasic. The aphasia was largely of a sensory type, and was persistent. The aphasia consisted principally in a word- and letter blindness which was due to a lesion in the right side of the brain. A systematic effort was made to re-educate the patient. In his training both the word image and the letters method were used. In six weeks he was able to recognize nearly all the letters of the alphabet. He has shown a letter, made to pronounce it, to write it, to pick it out from other letters, and to try to picture it. Simple words were taught him at the same time in the same manner. All efforts made to have him spell out letter by letter the words with which he became familiar, were unsuccessful. His mental picture of a word was of its entirety. He could not recall its literal components nor spell it.—*Medicine.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery

THOMAS L. STEDMAN, A.M., M.D., EDITOR

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, February 3, 1906.

TUBERCULOSIS SANATORIA: DO THEY PAY?

A RECENT issue of the *Lancet* contains a symposium on this subject, the word "pay" being used in its therapeutic and economic aspects. Naturally a diversity of views is expressed, based apparently upon the personal relation of the individual writer to direct sanatorium work. But from such men as Douglas Powell, Broadbent, Williams, Fowler, Wethered, Latham, and Walters, we may look for a dispassionate discussion of this popular question. In a general sense the verdict is far and away in favor of sanatoria. That they are expensive no one denies. That they attack the tuberculosis problem on the side of the effect rather than on that of the cause, is admitted. Yet the educational work which goes on in all well-ordered sanatoria and the fact that their graduates are missionaries of good hygiene, is not overlooked.

Douglas Powell declares that the "employment of sanatoria in the treatment of phthisis is now recognized as essential for the great majority of cases, for the reason that few people even amongst those who are fairly well-to-do can command those conditions of locality, house facilities, garden space, nursing help, and medical supervision which are the important elements of the treatment. And even amongst the more favored minority there are some who, having country houses with suitable aspects and other requirements, yet find the family conditions of life and temperament incompatible with restful home treatment. As regards the working classes, so discriminated against is consumption in our hospitals, institutions, and convalescent homes, that there is no alternative between the workman's own home or the scanty special hospital accommodation that exists and treatment in sanatoria." More attention should be paid to the matter of providing suitable employment for patients, so that they shall not become demoralized by a six months' idleness. Moreover, the majority of those who are benefited cannot return to the conditions under which they have broken down without the probability of a relapse. Experience shows, however, and most hopefully, that while they may return to the same general conditions they are often able to create, in view of their increased hygienic knowledge, a new environment for themselves.

There is a general opposition by the writers named to the erection of costly buildings. What constitutes a costly building depends entirely on one's own conception of that term. Mere architectural adornment falls under the ban, but every institution should have at least one substantial building, containing the administrative features, cooking arrangements, laundry facilities, etc., which can be depended on in all seasons and every kind of weather. Around this the more temporary structures may be grouped. Moreover, sanatorium results must inevitably be disappointing unless we make a sharp distinction between incipient and advanced cases, and segregate them accordingly. The good results reported from Saranac and Ray Brook in our own State are due in no small measure to an observance of this rule. It is useless to send patients, who ought to be at home in a hospital, miles away to a sanatorium, though, as one of the writers in the *Lancet* pertinently suggests, every general hospital and every special (chest) hospital should be in relation with a sanatorium.

Statistical evidence on all these points is in some respects contradictory, but on the whole it is decidedly encouraging. We must not pin our faith only on results achieved when the patients are leaving the sanatorium. The crucial point is as to the later history of these same patients. On this latter point Wethered writes as follows: "The majority of the patients who entered the sanatorium in the early stages of the disease and remained a sufficient length of time there will probably have been discharged as 'greatly improved and fit for work.' Other patients will have been sent out as 'unfit for work,' and advised to 'take things as easily as possible.' Inquiries into the future of these two classes yield peculiar results. According to statistics at the end of four years, about an equal percentage are alive and able to do light work. The explanation is that those who were discharged 'fit for work' returned to hard and unsuitable labor and surroundings, and many of them speedily relapsed, whilst those 'unfit for work' led quieter and more sheltered lives, capable, perhaps, of undertaking a little light work, and being carefully looked after by their friends or charitable institutions. They were thus able to drag on through an invalid life and did not suffer from severe recrudescence of active disease."

In both England and America the sanatorium treatment, especially among wage-earners, is perhaps too recent to allow of entirely dispassionate views. This much may safely be said, however, that it has yielded better results than any other plan thus far tried, and it has given a powerful reflex stimulus to the antituberculosis crusade, which is attacking this scourge of the human family all along the line.

A NEW DEFINITION OF MEDICAL PRACTICE.

MANY men, on the bench and off, have essayed to give a satisfactory definition of medical practice. Some have more nearly succeeded than others but none has evolved one that would, but for certain untoward circumstances, have given greater comfort to the "healers" and professors of the countless "pathies" of the day than Judge Deuel of *Town Topics* notoriety. A "naturopath," inappropriately named Allcutt, was recently convicted, in the Court of Special Sessions in this city, of illegally practising medicine, and was fined $50. Two of the justices concurred in this decision, but the third, Judge Deuel, handed down a dissenting opinion to the effect that the defendant did not practise medicine

and should therefore have been acquitted. The grounds of this opinion were that, "Outside of the finger tip treatment (the passing of the hands) he used nothing but 'old woman' remedies. A layman knows that a few spoonfuls of salt and water are harmless and that abstinence from pork, potatoes, and sweets may be beneficial. He examined the patient by asking questions, looking at her tongue, feeling of her pulse, listening to her heart and lungs, and then made a diagnosis. He said she had 'stomach trouble.' . . . But doing nothing but making a diagnosis and regulating the diet is not 'practising medicine.' Does all combined, diagnosis, salt and water, regulation of diet, and treatment, make out a case? Two of my associates answer in the affirmative. I dissent. . . . What the defendant did was as harmless as if, following diagnosis, he had said: "You have a cold. Go home, soak your feet in hot water, and go to bed"; infinitely less harmful than the tons and tons of so-called 'patent medicines' glaringly and speciously advertised as specifics for all manner of human ailments and yearly taken into the systems of the credulous."

This opinion, it is said, will be made the most of in support of the annual osteopathy bill in the New York State Legislature this winter, but we question whether it will carry as much weight as the supporters of the bill hoped it would when it was delivered. The author of it has since had an experience in another court—not on the bench—which has not enhanced his reputation for wisdom or widened his influence as a jurist.

The attitude of the medical profession in regard to the followers of a special mode of treatment, whether they are naturopaths, hygeiapaths, optometrists, or what not, is reasonable and consistent. Let all would-be practitioners, of whatever ism or pathy they may be, acquire a knowledge of the human body in health and disease, and prove the possession of this necessary knowledge by an examination before a legally constituted board of medical examiners—then let them treat disease in the way that seems to them best. There are many legally qualified practitioners who treat disease with few drugs, relying chiefly upon hygienic, dietetic, or hydrotherapeutic means. Medicine is unfortunately not yet a certain science, and no physician is compelled to give quinine in malaria if he does not see fit to do so. All that the profession demands is that he shall be properly instructed in the science of medicine as it exists to-day—the application of this science must be left to the individual judgment. There are good doctors and poor doctors, therapeutic optimists and therapeutic nihilists, but the law cannot discriminate between them, and does not pretend to prescribe rules of therapy; all it can do is to make sure that every man who essays to treat the sick possesses the necessary qualifications. It cannot eliminate the personal equation in medical practice any more than it can in other forms of human activity. It presumes, however, and justly, that a man who possesses a knowledge of medicine in all its branches is better qualified to treat disease than is one who does not. Such knowledge can do no harm to the conscientious opponent of drug treatment, and it surely would not render him less fit to practise intelligently his special form of therapy. If Mr. Allcutt will take a course of medicine in some recognized school and will then prove to the Board of Medical Examiners that he is qualified to practise medicine, he can return to his method of "finger-tip treatment," the prescribing of "a few spoonfuls of salt and water," and regulation of the diet, if he will—but he would not be likely to do so.

There is good in mental healing and there is good in osteopathy. The elder Charcot confessed that he had sent many patients to Lourdes, and we know of medical practitioners of the highest standing who have allowed their patients to submit to osteopathic treatment; but the special form of treatment was prescribed intelligently and because it was believed to meet the special indications in the individual case. The open-minded practitioner of medicine is catholic and rejects no therapeutic measure which he has reason to believe or to hope will benefit his patient, but, being catholic, he is unalterably opposed to any narrow system of therapeutics based upon insufficient knowledge of the science of medicine in all its branches. There is but one door through which one can enter upon the practice of medicine, and the attempt to climb in by the window is a confession of ignorance of the foundations of the healing art.

A Silly Bill in Ohio.

An old man with a stomachache will be in a parlous state in Ohio if Miss Anna S. Hall and Representative Hunt of Cincinnati have their way. The latter, presumably at the instance of the former, has introduced a bill into the Ohio House of Representatives, making it lawful "to kill a person suffering from intense pain and for whose recovery there is no hope." Everyone who has experienced it will fully admit that the pain of a stomachache may be intense, and no one will deny that there is no hope of recovery from old age. It is true, the bill provides an imaginary safeguard in that the patient's consent must first be obtained by some one who is not a relative or a presumptive heir; but a man, or a woman, with a pain legally defined as intense, may temporarily be *non compos* and weakly answer in the affirmative—and then the game is up. It is hardly possible to treat this question seriously, for it is too hideous to be regarded as anything but a grim joke. It is within the knowledge of almost everyone that some relative or friend, now living, has been believed, and even declared by the physician in attendance, to be beyond the hope of recovery. Consumptives, who once were gasping for breath and were momentarily expected to yield up their last sigh, are to-day leading an active and useful life; persons suffering from a tumor, pronounced cancerous and incurable by a council of physicians, have recovered and are carrying on their work with comfort to themselves and cheer to their families; the same is true of innumerable others who have been condemned to speedy dissolution and are yet alive to shame their doctors and rejoice their loved ones. "While there is life there is hope" is a saying so true that to deny it is an absurdity. There is a power in therapeutics, and a still greater power in the recuperative forces of nature, which it is inane to ignore. The Ohio legislators failed to reject this bill, when a motion to that effect was made, by a vote of 79 to 23, but we refuse to believe that this is a measure of the intelligence of this body of Solons. The seventy-nine may have thought it would be well to have some discussion on the subject before the

final rejection of this criminal suggestion, in order to instruct fool legislators in other States who might be contemplating a similar move, or they may have had some other motive; but that seventy-nine out of 102 men in any assembly outside of a lunatic asylum can seriously support this bill, which one sane member called "an insult to the intelligence of the House," passes the bounds of credulity. The thing is a silly joke, and we are unable to regard it as anything else.

The Retort Courteous.

Taking them by and large, the country over, it is probable that physicians are no more given to bumptiousness or to being puffed up in their own conceit than are the members of any other class or profession. Still an objective expression of opinion is always of benefit, and it may interest those who like to view themselves as other see them, to know the position in the ranks of toil accorded to physicians by some presumably intelligent, though hardly discriminating, laymen. In an editorial appearing on January 20 in the *Clinton* (Mass.) *Daily Item*, of which one of the trustees of the Rutland Sanatorium is the editor, it was stated, regarding the summary and apparently wholly unjustifiable dismissal of Dr. Bowditch, the superintendent of the institution, that the physician "was an employee of the trustees, just as their farmer or coachman is, and the Board therefore supposed it was at liberty to hire him or dismiss him at its pleasure." We are willing to concede that the men responsible for this high-handed exercise of authority must be hard put to it to find satisfactory reasons in explanation of their action, but it seems scarcely likely that a reply of the nature of the one quoted will better their position in the opinion of either the profession or the public.

A Triumph of Newspaper Medicine.

The medical editor of one of the New York dailies used often to say that medical journalism was played out, for a journal published only once a week or once a month could never compete with the daily papers; at best it could only republish in more elaborate, if less sensational, style what the lay press had printed days before. In view of a tremendous "beat" scored by the *Sun* last week, we are inclined to think the medico-lay editor was very nearly right. This enterprising journal published an interesting and circumstantial account of an operation for renal calculus, performed at one of the hospitals by a well-known surgeon of this city. All the details of the operation were graphically and, as it appeared the next day, quite accurately described. The point of special interest in the article was that the operation which it described was not performed until about twelve hours after the article had been published. "If you see it in the *Sun* it's going to be so."

Northampton County (Pa.) Medical Society.—The seventy-fifth annual meeting of this society was held at Easton on January 19 and the following officers were elected for the ensuing year: *President*, Dr. A. D. Raegan, Easton; *First Vice-President*, Dr. F. J. Hahn, Bath; *Second Vice-President*, Dr. H. C. Pohl, Nazareth; *Secretary and Reporter*, Dr. J. J. Quiney, Easton; *Corresponding Secretary*, Dr. J. E. Fretz, Easton; *Treasurer*, Dr. J. S. Hunt, Easton.

News of the Week.

The Cartwright Lectures.—The first of the three Cartwright lectures of the Alumni Association of the College of Physicians and Surgeons of New York, given by Baron K. Takaki, ex-Surgeon-General of the Imperial Japanese Navy, was delivered at the Academy of Medicine on January 25. The subject of the address was the prophylaxis of beriberi in the Japanese Navy. When he entered the service in 1872, Baron Takaki said the ravages of the disease were so serious that it appeared almost impossible to maintain the forces in fighting trim, and it was not until ten years had been spent in investigation and experimentation that satisfactory progress was made in preventing the malady. After numerous extensive studies in various directions, Baron Takaki was able in 1882 to announce definitely that beriberi was a disease of faulty nutrition and depended on a disproportion in the proteids and carbohydrates of the sailor's dietary. Rice and other carbonaceous foods preponderated, to the exclusion of proteids, largely owing to the practice of allowing the men to provide their own meals. They were allowed 18 sen each per day for the purpose, and they purchased the cheapest foodstuffs obtainable, in order to save a little pocket money out of their allowance. The diet had now been changed to one more rich in nitrogenous materials, and though the cost of feeding had been more than doubled, beriberi had become practically extinct.

The second lecture was delivered on the evening of January 29, the subject being surgery and surgical nursing in the navy. In Japan the Bureau of Medicine and Surgery constitutes one of the five naval departments. The training of the naval surgeons embraces the study of naval hygiene, construction of ships, epidemic and endemic diseases of all countries, especially along the coast; several foreign languages, dentistry, photography, medical electricity, disinfection, and methods of examining food. Nurses, in addition to the ordinary courses, are taught rowing, gymnastics, swimming, and pistol shooting. The Japanese surgeons in both branches of the service, he said, were sanitarians as well as practitioners, their aim being to prevent disease as well as to heal wounds. It was as important to select proper food for the men as good powder for the guns. The powder always had to be up to a definite standard, and it should be the same with the food. Up to December 5, 1905, the total casualties in the Japanese navy, as a result of the Japan-Russia war, amounted to 3,689, of which number only 700 occurred in the battle of the Sea of Japan when the Baltic Fleet was destroyed.

Health Conditions at Panama.—According to the report for November of Chief Sanitary Officer Col. Gorgas yellow fever has been practically eliminated from the Canal Zone, and malarial infections have been reduced to a minimum. In the seventeen months between July, 1904, and November 30, 1905, in Panama, Colon, in the Canal Zone, including all persons traveling to and fro between various ports, there were only 245 cases of yellow fever and 84 deaths. Within this period, of the employees of the Commission appointed in the United States 72 had yellow fever and 16 died. Of those appointed on the Isthmus 44 were taken ill with the disease and 11 died. Among the employees of the Panama Railroad Company there were 17 cases and 7 deaths; of those not employed by the Commission or the Panama Railroad Company, 112 cases and 50 deaths. For the month of November, 1905, there were in all this region only three cases

of yellow fever, and none of these were employees of the Government in any capacity. One occurred in Panama and two in Colon.

Two Sufferers from Appendicitis.—Dr. George R. Fowler of Brooklyn, who went to Albany to attend the meeting of the Medical Society of the State of New York, was taken ill there with symptoms of appendicitis, and was operated upon on Monday. On Friday of last week Dr. Andrew J. McCosh was successfully operated upon for the same condition at the Presbyterian Hospital, in this city.

New York State Hospital for the Care of Crippled and Deformed Children.—The fifth annual report of this institution shows that fifty-six patients were treated during the twelve months covered by the report, most of the patients suffering from tuberculous joint disease. The hospital has received a contribution of $500, to be used for transporting eligible, indigent patients living in especially the rural districts of the State to, and from the hospital. Applications for admission, accompanied, if possible, by the certificate of a physician as to the nature of the deformity, should be addressed to the Surgeon in Chief, New York State Hospital for the Care of Crippled and Deformed Children, West Haverstraw, N. Y.

Reception to Dr. R. T. Morris.—At a stated meeting of the Section on Gynecology of the College of Physicians of Philadelphia, held January 18, Dr. Robert T. Morris of New York read by invitation an address entitled, "A General Surgeon's Views on Some Pelvic Conditions in Women." The discussion was participated in by Drs. J. G. Clark, E. E. Montgomery, C. P. Noble, B. C. Hirst, T. R. Neilson, J. M. Baldy, John B. Deaver, and others. After the meeting a reception was tendered Dr. Morris by Dr. W. Reynolds Wilson.

California Appointments.—Dr. J. W. Ward, on January 8, was reappointed a member of the San Francisco Board of Health, and was at once re-elected president of the board. Drs. Arthur T. McGinty, W. M. Lawlor, and M. E. Magnus were appointed assistant surgeons in the emergency hospital service. Dr. William Quinn was made resident physician at the city and county hospital and Dr. Mary Halton was appointed volunteer inspecting physician at the girls' high school. Drs. Garrett Newkirk of Pasadena, and J. L. Pease of Oakland have been appointed members of the State board of dental examiners to succeed Drs. R. Cole and J. M. Dun, of Oakland.

The Harvey Society Lectures.—The seventh lecture in the Harvey Society course will be delivered by Prof. Frederick S. Lee of Columbia University on Saturday evening, February 3, at 8.30 o'clock, in the hall of the New York Academy of Medicine. The subject of the lecture will be "Fatigue". The eighth lecture will be delivered by Prof. L. B. Mendell on Saturday, February 10, at the same place and hour; the subject will be "The Formation of Uric Acid."

New York City's Milk Supply.—According to a report of the Department of Agriculture the average consumption of milk in the city exceeds half a pint per capita a day, or 875,000 quarts. If the cream consumed were estimated on the same basis as the milk, the industry would be shown to amount to over 1,500 quarts daily, for which more than 200,000 cows would be required. The report censures the manner in which the smaller dealers store their supply of milk, and it is stated that out of a total of 2,458 stores visited, only 454 were found where the milk was properly cooled, and where there was no communication with living rooms.

Rhode Island Homeopathic Medical Society.—This society held its fifty-sixth annual meeting at Providence on January 12. All of the officers were reelected, the list being as follows: *President*, Dr Cornelius J. Hasbrouck; *Vice-President*, Dr. George F. Allison; *Secretary*, Dr. Robert S. Phillips; *Treasurer*, Dr. Jeannie O. Arnold.

An Outbreak of Scurvy.—The German ship *Alsternixe*, from Hamburg, drifted into Santa Rosalia, Lower California, with the fifteen surviving members of her crew seriously ill with scurvy. Owing to adverse conditions, she had been out six months. The captain died at sea.

The Illinois State Board of Health.—At the twenty-ninth annual meeting of this Board on January 25, the following officers were elected for the ensuing year: *President*, Dr. George H. Webster of Chicago; *Secretary and Treasurer*, Dr. James A. Egan of Springfield.

A Gift to Science.—The Marine Biological Association of San Diego, Cal., has received a donation of $50,000 from Miss Ellen B. Scripps, one of its most enthusiastic members. This will be applied to the building of a magnificent laboratory and museum at La Jolla, one of the most picturesque suburbs of San Diego. Dr. W. E. Ritter, of the University of California, who is in charge of the biological investigations at this station, will leave in a few weeks for an extended tour of the orient.

Examinations for Civil Service.—An examination will be held this month by the Illinois State Civil Service Commission for attendance in the seven hospitals for the insane. The examination will be open to women between the ages of eighteen and forty-five years, and to men between twenty-two and forty-years. The subjects on which applicants will be examined and the weights or basis of marking will be: Common school requirements, 3; physical examination, 4; and oral examination as to qualifications, 3. The examining board consists of Dr. Harry G. Hardt, assistant physician at the Illinois Northern Hospital for the Insane, Elgin; Dr. Herbert A. Potts, assistant physician, Illinois Central Hospital for the Insane, Jacksonville, and Miss Nellie Fitzgerald, head nurse, Illinois Eastern Hospital for the Insane, Kankakee.

Civil Service Examination for Pathologist.—The State Civil Service Commission announces an examination to be held about March 1 for Pathologists at the Craig Colony for Epileptics, with a salary of $2,500 and maintenance. Application forms and detailed information may be obtained by addressing the Chief Examiner of the Commission at Albany.

Philadelphia County Medical Society.—At the business meeting held January 17 the following officers were elected for the ensuing year: *President*, Dr. Chas. K. Mills; *First Vice-President*, Dr. Jas. B. Walker; *Second Vice-President*, Dr. A. O. J. Kelly; *Third Vice-President*, Dr. L. J. Hammond; *Fourth Vice-President*, Dr. A. B. Hirsh; *Fifth Vice-President*, Dr. Chas. A. E. Codman; *Sixth Vice-President*, Dr. Jas. C. Chestnut; *Secretary*, Dr. Wm. S. Wray; *Assistant Secretary*, Dr. Ross H. Skillern, *Treasurer*, Dr. Collier L. Bower; *Censor*, Dr. Frederick P. Henry; *District Censor*, Dr. Albert M. Eaton.

River Tooting Nuisance.—After two extended hearings on the subject of the unnecessary whistle blowing by the captains and pilots of the river craft plying about New York City, the Board of Supervising Inspectors of the Steamboat Service at Washington has decided that under the present

laws the Federal government has no authority to abate or abolish the nuisance. The solicitor of the Department of Commerce holds that while the Government can and does prescribe signals, it has no power to prohibit the blowing of whistles if the masters or captains of vessels declare that it is necessary. The suggestion was made that the State authorities be appealed to, but as these have already shown themselves unable or unwilling to interfere, it appears that it will be necessary to approach the offenders themselves, *suaviter in modo*, in an effort to obtain by curtesy what it seems impossible to exact by force.

The Late Dr. Emmet Cooper Dent.—The following resolutions have been adopted by the Council of the American Medico-Psychological Association:

Whereas, By the death of our late associate, fellow member, and secretary, this Association has been deprived of one of its most worthy members and progressive workers, and,

Whereas, We, his associates, have lost a dearly-loved comrade whom we honored for his integrity, uprightness of character and sterling worth, whom we respected for his well-known high standards in professional and in ordinary living, whom we admired for his unselfish devotion to all that made for a higher manhood, and for his steady and unflagging interest in the suffering humanity to which he ministered, and whom we all loved as an ever loyal friend and companion; therefore be it

Resolved, That we extend to the bereaved family our heartfelt sympathy in their grief, and the assurance that his memory will ever remain cherished by us.

(Signed) Wm. Austin Macy, George A. Smith, Charles W. Pilgrim.

Obituary Notes.—Dr. Philip S. Orndorff of Rio, W. Va., died on January 16, at the age of seventy-two years. Dr. Orndorff was born near Winchester and served with distinction in the Confederate army. He had practised medicine for nearly forty-one years in Hampshire County.

Dr. Norman R. Miller of Lynn, Mass., died on January 18, after a year's illness, at the age of forty-seven years. Dr. Miller was born in Springfield, and received his medical diploma from the College of Physicians and Surgeons of New York in 1881. He practised for a time in Holyoke, and went to Lynn in 1884. Three years ago he sold his practise and accepted a position as superintendent of a sanatorium for nevous diseases near Boston.

Dr. B. F. Watkins of Bryan, Tex., died on December 25, at the age of seventy-three years. His illness began with a stroke of paralysis while performing an operation in 1902, and he had never been well since then. He was a native of Alabama and was graduated from Yale College, the University of Pennsylvania, and Bellevue Medical College, New York. He served through the Civil War in the Confederate army.

Dr. George Chismore of San Francisco died of pneumonia on January 11, at the age of sixty-six years. He was born in Ilion, N. Y., and went to California in 1854. He engaged in mining for a time, but later took up the study of medicine, and in 1872 received his diploma from the Cooper Medical College. He served for a time as acting assistant surgeon in the United States army and developed a large practice in genitourinary disorders in San Francisco.

Dr. A. L. Hersey of Oxford, Me., died in Boston on January 12, after an illness of only two days. He was graduated from the Medical School of Maine at Bowdoin College in 1853.

Correspondence.

THE SURGEON'S FEES.

To the Editor of the Medical Record:

Sir:—The correspondence relative to the fee question, which I published in the Medical Record for January 6, has called out a good deal of response—from editors, who gave the subject good analysis, to correspondents, medical and lay, who wrote letters to the editors. Please allow me to answer some of the points which seem to indicate that the writers are not quite familiar with this matter of the fee.

"The surgeon's skill is something that any intelligent man can acquire in the same length of time that he would require in architecture, civil engineering, or the law."

Answer.—Given two surgeons of equal standing, and a certain kind of operation. One surgeon's death-rate may be 2 per cent., and the other surgeon's death-rate 20 per cent., in a series of one hundred cases of operations of that particular sort. I imagine that buildings sometimes tumble, bridges give way, and law clients get into trouble, in cases in which Providence does not have to work alone and unaided.

"A student who is bent upon acquiring a special education can do so in four or five years very comfortably on $1,000 a year. At the rate of $1,000 an operation he would be able to pay for his whole education in sixty minutes."

Answer.—It was recently reported that statistics of a class ten years after graduation from one of our leading medical colleges showed that only 40 per cent. of the class remained in active practice, and I was informed on a trip through Ohio not long ago that 87 per cent. of all graduates in medicine had dropped out of practice in that State during a period covered by statistics. This would indicate that not all of the men who had spent several years in medical education at an expense of $1,000 per year, had found opportunity to pay for the education in sixty minutes.

"The patient takes all of the responsibility. He pays all the expenses of nurses, etc. When everything is ready, the surgeon comes in and does something that requires no more skill than filling a tooth, or hitting a bullseye at 300 yards, or drawing the plan of a house."

Answer.—Of the physicians who remain in active practice, about one-half have been ambitious to become surgeons, and have given themselves expensive special training. A fraction of 1 per cent. find in the end that they are adapted by nature for the life of the surgeon. The responsibility is so great that many of the best-equipped men are unable to carry it. The patient's responsibility should end when he has made a choice of the general practitioner who is to direct the selection of specialists. The physician then feels that the responsibility is all his own; but the surgeon who is called in feels so responsible to the patient, to the physician, and to the profession, that few remain to carry on that sort of work.

"If the patient dies, the surgeon's reputation is not materially damaged."

Answer.—I have under my care at the present moment two patients of notable social prominence who came from two cities in which there are surgeons of the first class. The reason that the patients gave for coming to me was that their surgeons had lost similar cases. If these patients remain in New York long enough, they will learn that I have also lost patients in similar cases. Meanwhile there is material loss for two surgeons in other cities.

"The idea that a surgeon should charge as much as he thinks the patient can afford is wrong. It fosters on the part of the surgeon a rapacity wholly at variance with the ideals of his profession."

Answer.—The surgeon customarily charges less than he believes the services to be worth, because he knows that the laity will not understand, and the physician who has called him may be subjected to criticism. We are usually weak on this point, to the injury of the dignity of our calling. If this correspondent fears that his doctor will call in a rapacious surgeon, he needs only to give the tip that inexpensive work is the sort desired, and his doctor can get it for him.

"Wealthy emotional people form the basis upon which high prices are created."

Answer, with three specific instances. Last year a physician from the western part of the State came to the office of Dr. X. with a gallstone patient. The physician had previously written Dr. X. that the patient would pay $250 for the operation, if one was decided upon. On personal interview Dr. X. perceived at once that the patient was a blunt-spoken, direct man of affairs, of the sort to whom one can speak outright and freely. He was told that there was something wrong about the proposed fee of $250, and was asked how much he was paying his physician for time and responsibility. The physician said that

he was not making any charge at all. The patient was a friend of his and it was worth the trip to the city to see the operation. Dr. X. said to the patient, "I am going to tell you exactly what I think, and you are at liberty to agree or to disagree. You should pay me $1,000 for the operation, and pay your physician the $250 besides, for his time and responsibility." The patient instantly agreed. There was not a moment of hesitation.

Here is a case of another sort. One that we hear a good deal about, but seldom actually see. It involves the same figures as the first case. A physician came to the office of Dr. X. from Iowa with a patient requiring excision of the superior maxilla. After the consultation, he took Dr. X. aside and said that the patient was prepared to pay $1,000 for the operation, and that $250 would be acceptable as his part of the fee. Dr. X. replied that he was perfectly willing to quarter or even to halve the fee, provided that the patient was aware of the transaction. Otherwise not a cent would be given. The physician was unwilling to have his patient know about any division of the fee, and took him elsewhere. Dr. X. learned subsequently that the physician was unable to get his patient operated upon in New York. If we are so rapacious that we can afford to keep the profession clean, the law of compensation works out pretty well after all, does it not?

The third case in illustration is this: Five or six years ago Dr. X. refused to operate upon an interval case of appendicitis with adhesions, for less than $10,000. The patient secured the services of another surgeon for one-half of that amount. Two years later he stated that he had made a mistake, as a complication that appeared had cost him much more than the amount of the originally proposed fee. He said that the larger fee would have been the better investment. That was the way in which a hard-headed business man looked upon the matter of insurance against complications. All three of these patients were wealthy. All three were in ignorance of what they were about. Not one of the three was emotional. On the contrary, they were all men who had ceased to make much response to impact from any quarter.

"What is a man of limited income to do if he values his life, or wishes to have the best skill for his loved ones?"

Answer.—Ask his family physician to see that he gets it. He can obtain the very best services with less trouble or bargaining than is often required for obtaining mediocre or harmful services. Experts who put the highest value upon their services are the ones to whom I send my patients with small means, and I have never known one of them to be caused any deprivation. Sometimes they have even had their hospital expenses paid for them, beside a special expense account for various examinations. If it was felt that their pride would be hurt by a knowledge of the fact, they were never informed about it.

"The surgeon should strive to render service for fees which will allow friendly relations to remain between him and the patient."

Answer.—This is an old idea which belonged to the days when kind men did the wrong things, and when the surgeon's training was not expensive. To-day some of us do not care whether we part as friends or as enemies, so long as we get the patient well. We are interested in the physiology rather than in the psychology of our patients. There is gratitude and friendliness of the right sort, and we all enjoy it. There is so much gratitude and friendliness that is morbid, or that has a string to it, that a good healthy kick is more healthful and refreshing. Is there a doctor who will deny this statement?

"The surgeon exceeds in one line, the general practitioner in another, equally high grade, and as representative of ability, effort, and time given to perfection."

Answer.—Granted! Take, for instance, a case of "dyspepsia" in a man of large and varied interests, whose working capacity is limited by his ailment. If the general practitioner recognizes the fact that dyspepsia is a symptom rather than a diagnostic entity, and that it means a functional disturbance for which a cause is to be found, he may send the patient to an ophthalmologist to determine if eye-strain is at the bottom of the trouble; to a neurologist in the effort at finding a central neurosis; to a gastrologist in order to get data upon the objective features; to a hematologist to learn if there is toxemia from defective metabolism; to a pathologist to learn the significance of characteristics of the excreta; to a surgeon to know if an involuting appendix or bile tract adhesions are present in the case and likely to furnish the precipitating factor. If the general practitioner goes at his cases in this way my argument is not that his fee should be less than that of the surgeon, but quite as large. An important part of the general practitioner's work consists in surrounding himself with experts in whom he has confidence. This in itself requires years of experience with various experts, and calls for proper compensation on the part of the patient who would avail himself of the physician's experience. I often wonder if the public is awake on this point.

"There are many country surgeons, and young men, who can do an appendicitis operation quite as well as the experts, and at a small part of the expense."

Answer.—The two surgeons who perhaps have the largest general surgical practice in America to-day live in a small town that was unheard of until they showed the profession what they could do, and placed the town upon the map. There is many a young man doing brilliant work who is not as yet known, or who has false ideas of modesty about letting us hear of him to our own advantage. If a patient wishes to have the inexpensive work of such a man, all that is necessary is for him to instruct his family physician to engage himself in the task of finding the men who undervalue their services, but who can, nevertheless, do as good work as that which experts have set before the critical jury of their peers.

"My physician called in a consultant after he had confessed his own ignorance about the case. The consultant charged $100, but did not do any good. Why should I not have discharged my own physician after he had confessed his own ignorance, and not have had both bills to pay?"

Answer.—This correspondent is either a "quitter," or else he probably received full value for services rendered without being aware of the fact. If he dropped his own physician just as soon as he found that consultants were to be called, he deserves to suffer the consequences. If his own physician, unable to help, called in a competent authority who determined that no one could help, the patient is now spared the expense and anxiety of future fruitless search, and his own physician is entitled to a fee for his services in bringing the expense account to a close. It required experience and knowledge of a high order to get the right decision.

"Surgeons like Dr. M. should not be sustained by the general practitioner, because he breeds the anarchistic and socialistic spirit with his fees."

Answer.—I know a good many surgeons and physicians who would be willing to work for one-fourth of their present incomes if the public would furnish funds for scientific or educational work in which they are interested, and toward which their professional incomes are bent in an altruistic way. All that they ask for is power for being useful to their profession and to the public. About two years ago the editor of *Science* summed up the testimony of correspondents on the subject of the Carnegie fund for scientific research, and he decided that the income from the fund would further about one per cent. of the objects for which it was intended. If the laymen will ask almost any rapacious physician or surgeon of recognized standing what salary he would accept for his personal use, provided that he could have the Carnegie fund at his disposal for research or educational work, the answer is likely to cause surprise.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SANATORIUMS—VITALITY OF A NATION—PATHOLOGY AT OXFORD ENDOWMENT—MOTOR AMBULANCE SCHEME—HOSPITAL FIRE—CELLULOID—SUICIDES—OBITUARY.

London, January 12, 1906.

Last month at the Liverpool Medical Institution a discussion was opened by Drs. Buchanan and Macalister with the question often asked here, "Is the Sanatorium Treatment of Consumption Worth While?" Dr. Buchanan suggested that there is some internal power working toward recovery in consumption as in other infective processes and that stimulation of this power might assist. This seems a vague indication, but he followed it up by urging early treatment upon principles based on our knowledge of etiological factors and of the effects of hygienic and dietetic treatment. Those principles, he said, admitted of no discussion and were best carried out in a sanatorium worthy the name by a medical man who thoroughly believed and enforced them in a systematic and exact manner with due respect to their truth and importance. His personal experience, he declared, enabled him to say he knew of no treatment so invigorating, so sensible, and so trustworthy and which held out so much hope and encouragement or afforded so good a prospect of success.

Dr. Macalister followed with a very different story. His experience had been disappointing. Although many cases had been treated in the early stages, a relapse had subsequently occurred in nearly every one. He regarded the treatment of the poor in such institutions as utterly futile, and said those who subsequently died from pulmonary tuberculosis did so in about the same period as they would have done had they never been in a sanatorium. The death rate had not diminished to any great extent since the advent of sanatoriums; in fact, the death rate and recovery rate were about the same as before, both in and out of the

institutions. In some of the most successful cases there was a strong tendency toward recovery, and this had more to do with the event than any treatment. He advocated inexpensive buildings. The great problem was the prevention of infection.

Dr. Colin Campbell lamented the contradictory and inconclusive statistics, the confusion as to classification, and the vagueness of the reports of so-called cures. Favorable results lay somewhere between the 60 per cent. of "economic cures" reported from Germany and the 3 out of 38 cases reported from Heswall as "arrested."

Dr. Crace-Calvert said statistics were adversely affected by the short stay of many—often six weeks, or even less—and by the kind of work and unsuitable surroundings to which the patients returned. He was for early treatment of incipient cases, to be followed by a time in the country, as then the patients had learned to carry on their treatment and much time was saved.

Dr. Ernest Nevins said when public bodies are urged to erect sanatoriums we may well ask, "Is it worth while?" From the point of view of social economy the reply must be unfavorable. Enthusiasts blame unsuitable cases for bad results, but the conditions to make cases suitable are impossible for the majority, and it is useless to teach a man a mode of life which he will never be able to follow out.

In reference to the subject of sanatorium treatment, the *Lancet* this week gives a sort of symposium by London physicians who are recognized as authorities. The articles are founded on questions submitted by the editors on several points of importance, but on which a definite reply was not expected and each writer was to take his own line. The collected essays form an interesting exposition of the current opinions on the subject. That sanatoriums are regarded as extremely valuable institutions is obvious; that there are limits to their usefulness must be admitted. Most advocates think that convalescent homes, or country colonies, are desirable for prolonging the treatment, and some consider such supplements necessary. There seems to be a reaction against the erection of costly buildings and a tendency to look at the subject from an economic point of view. The combination of insurance with sanatorium treatment, as in Germany, seems to some an essential part of a successful scheme, but while so holding it they do not see how it is to be accomplished in this country. It is suggested that statesmen might elaborate some form of co-operation between trades unions, provident and charitable societies, and so utilize enormous sums for the war against consumption. But most of these sums are already ear marked and politicians are too engrossed in their party disputes to study sanitation.

Dr. Hyslop of the Bethlehem Hospital takes rather a gloomy view of the state of the world, if one may judge from a paper on "The Vitality of a Nation," which he read on the 9th inst. at the Society for the Study of Inebriety. He said man's innate conceit leads him to claim exemption from the universal law of evolution and dissolution. But it may be argued that as all living organisms, and even worlds, live and die, so will he; as the universe is the tomb of dead and dying worlds, so is our earth the tomb of empires, and there is evidence of restrictions to the evolution of humanity; not only had mankind approached the summit of attainment, but is, perhaps, growing old. Our acquisitions and attainments, derived as they are from the artifices of civilization, he held to be not only impediments to true mental evolution, but tend to submerge and render less vital the human mental faculties. The rôle of alcohol was as potent in producing decay in a nation as it was in an individual. Therefore, we should put forth increased efforts to tackle this as well as every factor which is causing the empire to drift into premature senility and an early grave.

Dr. Rob. Jones thought his confrère too pessimistic, and regarded the increased altruism of the English people as a sign of progression rather than decay.

At Addenbrooke's Hospital, Cambridge, fire broke out about midday on Saturday. There was a heavy gale blowing, but fortunately it blew the flames away from the building or there would have been a disaster. The patients in two wards adjoining the room where the fire was burning had to be removed, and then the brigade subdued the fire.

At an inquest on a man who lost his life in a fire at a celluloid factory it was shown that, in spite of strict regulations, he was at work with a lighted candle in his hand. This the chief officer of the Salvage Corps considered criminal; and further this witness said he had lately found out that celluloid had been used for the heels of ladies' boots, and what would happen if a lady wearing such put her feet on the fender, he could not think.

The late Sir J. Burdon-Sanderson has left £2,000 towards the support of the Pathological Laboratory at Oxford for the purpose of research.

The Asylums Board is proceeding with its scheme for motor ambulances. One motor omnibus is in hand and others are on order. The southwestern district of London will soon have a complete motor ambulance service.

An octogenarian committed suicide on Tuesday. After a quarrel with his relatives, he said he would show them a trick, went upstairs, and was heard chuckling and laughing, but fell dead on the way down. He had swallowed prussic acid. The coroner's jury said temporary insanity, but did not seem to have inquired how he became possessed of the poison.

Mr. John Abernethy Kingdon, F.R.C.S., died during sleep in his 78th year, on the 5th inst. Mr. Kingdon was for many years surgeon to the Bank of England, close to which he resided. He had a further valuable clientèle among city men. He was also many years surgeon to the Truss Society. He was a Bart's student, took his M.R.C.S. as long ago as 1849, and was elected a Fellow in 1861. He had been vice-president of the Medical-Chirurgical Society, and contributed to the *Transactions*. He was also a member of the Pathological Society, a courteous gentleman, and most agreeable colleague on committees; he was much esteemed.

AMERICAN HOSPITAL ECONOMICS.

To the Editor of the Medical Record:

Sir:—I regret to state that the figure of daily per capita maintenance of patients at the Eppendorf Hospital, Hamburg, quoted in my address on Hospital Economy, is erroneous. My informant, perfectly trustworthy in his statements, as far as they went, was himself in error, inasmuch as his figures did not cover all the items that ought to be considered in computing total cost. The unquestioning acceptance by me of statements, put at my disposal in perfect good faith by a trustworthy friend, proved to be a mistake on my part, to which I must plead guilty.

Now as to the facts: According to the printed report of the managers of the Hamburg hospitals for the year 1904, the cost of daily maintenance of one patient at Eppendorf was 3 marks and 61 pfennige, amounting to about 82 cents, U. S. currency. Deducting from this the salaries of the medical officers, which amount to about one-twentieth (1/20) of the total expenditure of 2,276,230 marks, the daily per capita cost will be about 78 cents, which is more than double the figure quoted by me. If the salaries of the medical officers be not deducted, the figure will be 82 cents, nearly the treble of 30 cents.

The figure quoted in my address as the daily average for the large hospitals of Germany needs correction also, though it must be added that Eppendorf, being thoroughly modern, and being managed on advanced principles, is, like Nürnberg, one of the most expensively managed institutions.

Arpad G. Gerster, M.D.
34 East Seventy-fifth Street, New York.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 25, 1906.

A Study of the Larynx in Tabes.—D. C. Greene, Jr., reports his observations on sixty cases of tabes. Of these, nine, or 15 per cent., presented laryngeal complications; six, or 10 per cent., showed undoubted paralysis of one or both vocal cords; seven, or 12 per cent., were affected with laryngeal crises, three of these without evident paralysis of either cord. One presented a jerky movement of the cord in the excursion from the median line. The only form of paralysis observed was the abductor type. Of the six cases, five were unilateral and one bilateral. Three were partial and three complete as to degree. Greene notes that it is a remarkable fact that the paralysis should confine itself in the great majority of cases to the posterior cricoarytenoid muscle. The explanation seems to be that we have to do with a slowly progressive degeneration of the fibers of the recurrent nerve. The cord is drawn to the median line at first by contraction of the adductors, and later by actual atrophic shortening of these same muscles. Laryngeal crisis occurred in four cases with paralysis, and in three without. These crises are marked by pain and irritation in the larynx, followed by cough, dyspnea, and loud inspiratory stridor. Mild cases simulate whooping-cough. Death may occur in the severe cases. When present in the author's cases, they occurred among the earliest symptoms. We are justified in saying that the paralysis probably occurs early. Two clinical histories are given, in both of which examination of the larynx led to the diagnosis of tabes.

Contusions of the Abdomen.—Seven cases are reported by J. C. Hubbard. From a study of them he concludes that it is obvious that a patient who has received a blow upon the abdomen of any degree of force is in a critical con-

dition and must be under careful observation, for on slight changes in the physical condition depend the diagnosis and often his life. The absence of muscular spasm does not rule out an intraabdominal lesion, while its presence makes such a condition the more probable. Hot applications should be applied to the abdomen and the pulse recorded at frequent intervals. The urine should be drawn by catheter, if the patient is unable to pass it. Should the pulse rate steadily rise, even only slowly, or the abdominal spasm persist, or the urine be bloody, the case becomes distinctly surgical. The extent of the lesion produced bears no relation to the severity of the trauma. Of far greater significance is the condition of the abdominal wall; whether relaxed or contracted at the time of injury, the state of the bowel, distended or empty, and the length of time since the last meal or last micturition. Exact diagnosis must be secondary to the general diagnosis of abdominal trauma. In most of the operative cases the exact diagnosis of the nature of the intraabdominal lesion is not made till the operation, and in many of them it would be wrong to wait long enough to make such a diagnosis.

New York Medical Journal, January 27, 1906.

Intermittent Exophthalmus.—One case is reported by E. C. Alger, who gives a brief bibliography of the subject: True intermittent exophthalmus is a rare condition in which owing to changes in the orbital veins one eye is pushed forward to a greater or less degree out of the orbit into which it recedes again as soon as the venous pressure becomes normal, the process of recession being greatly hastened by pressure on the eyeball in front. Alger's patient was an Italian woman of 34 years, in whom the condition referred to came on suddenly as she was bending over to put on her shoes. She had nausea and vomiting, but the eye returned to its normal sight with vision unimpaired. Thereafter the accident was apt to recur whenever she placed herself in a constrained position, but the eye would replace itself if she straightened up. In one attack ice was applied to the eye and the patient later became blind. Whether the blindness was the result of the applications could not be determined. The author describes the minute details of the ocular condition. He notes as possible causes of the orbital venous congestion, anything obstructing return circulation and a weakness of the wall of the vein which might be either congenital or the result of disease. The treatment is largely palliative. Patients should avoid constricting neckwear, severe exertion, and postures tending to cause congestion of the head. A snug bandage may be worn several hours daily. If vision is failing and the attack does not subside speedily, exploratory incision into the orbit might reveal a clot or a varix. Palpation may locate the latter and the former may be suggested by the regular symptoms of retrobulbar hemorrhage.

Stool Examination in Starch Fed Children Under One Year of Age.—C. G. Kerley and W. C. Campbell report the results of 166 examinations made of the stools of 30 children. In order to make the test a severe one raw barley flour was used, cooked one and one-half hours. In some cases barley water formed the milk diluent; in others it was given plain. The technical methods followed are described in full. In 16 children the stool tests showed absence of starch from the evacuations. In 5 of these negative cases there was moderate and in 1 severe diarrhea. Three cases were persistently positive, that is, starch appeared in the stools. Of these 3, two had diarrhea. The remaining 11 cases were sometimes positive and sometimes negative to the starch test. Out of the entire 30 cases 23 showed a good capacity to digest starch. Of these 11 had diarrhea, seven showed a poor starch capacity. A reaction for dextrin was present at times in 10 children, having been found in 18 examinations. The authors interpret this reaction as meaning that dextrin was present in the stool, representing an incomplete starch digestion, due, perhaps, to the too rapid passage of the fecal contents, as it was present in several of the diarrhea cases, or it was due to a deficiency in diastatic enzyme, not enough being present in the intestine to produce a complete splitting up of the starch product.

Epidemic of Measles in Mexico.—B. L. Wyatt gives an account of this disease as occurring in the country named. Its clinical course differs but little from that observed in the United States. The prodromes in Mexico are generally less marked. The symptoms of the emptive stage are also less severe. Complications and sequelæ are neither so common nor so serious. Bronchopneumonia is rare. In the special epidemic referred to, enterocolitis was a common sequel; otitis media eczema and acne disseminata were all observed. The patients do well in spite of most unhygienic surroundings and customs.

American Medicine, January 27, 1906.

Some Problems in the Diagnosis and Treatment of Puerperal Infection.—B. C. Hirst asserts that but little progress has been made in the prevention, the recognition, and the cure of puerperal infection, though in frequency and danger it stands first among the diseases of women. He takes up in turn a full discussion of the bacteriologic examination of infected women as a means of precise and accurate diagnosis; the influence the results of this examination should have upon prognosis and treatment; the treatment of infection after labor by instrumental exploration and evacuation of the uterus; the present status of antistreptococcic serum as a curative agent; and, the lessons taught by practical experience in the operative treatment of puerperal sepsis by pelvic and abdominal surgery.

Intestinal Hemorrhage as a Fatal Complication in Amebic Dysentery, and Its Association with Liver Abscess.—Richard P. Strong reports four cases in which the fatal termination was due to this complication. The fact that in all the cases large liver abscess coexisted would seem to show that a close connection exists between intestinal hemorrhage and the hepatic condition. The idea that the destruction of such large amounts of liver tissue may sometimes bring about serious functional disturbances of this organ and lead to a condition which predisposes to hemorrhage must certainly be considered. While it is probable that more extensive observations will show that fatal intestinal hemorrhage in amebic dysentery may occur entirely independently of liver abscess, the cases to which Dr. Strong has referred would seem to show that at least when hemorrhage occurs in cases complicated with such hepatic disease it is likely to be very severe and that the bleeding is likely to recur. It is possible also that the occurrence of multiple intestinal hemorrhages in amebic dysentery may be occasionally of some importance in the diagnosis of liver abscess.

Diphtheria Antitoxin in Scarlatina.—J. H. Lopez finds that early curative doses of diphtheria antitoxin administered in scarlatina abort the disease, curtail suffering, and lessen the risk to the patient, one dose of 2000 units, being sufficient in the average case of sore throat due to bacterial infection, to effect a speedy cure. He also finds the serum equally effective in all anginas, be they scarlatina, tonsillitis, quinsy, etc., through neutralizing the toxins, and reducing the fever and local congestion which contribute to the patient's suffering and the element of danger. There are no contraindications, and only good follows such practice. Dr. Lopez states it should be remembered that the largest quantities of serum the most severe cases may require, running from 20,000 to 100,000 units, are not depressing to the heart, are not attended with any bad results or sequels, and are without a single element of danger. The author's experience is based upon private practice, and upon results obtained in an orphanage containing over 300 children, where there were many cases of scarlatina.

Chronic Enlargement of the Tonsils as a Factor in Etiology.—C. P. Nelson points out that enlarged diseased tonsils play an important part as portals of infection to the respiratory and digestive tracts. As chronic enlargement of the tonsils is very prevalent and as it leads to such dire results the physician should always be prepared to operate promptly, when necessary. This operation should be done as quickly, painlessly, and safely as possible. In view of the large number of deaths due to diseases of the respiratory tract, mostly caused by bacteria in the inspired air, it becomes imperative that we guard well the entrance thereto.

Journal of the American Medical Association, January 27, 1906.

Chorionepitheliomatous Proliferations in Teratomata.—R. T. Frank reviews the literature and theories of chorionepitheliomatous growths and metastases other than those in connection with the pregnant condition, and especially of those of the testicle. The theory favored by the author is that of Marchand and Bonnet, which assumes their origin from impregnated pole cells or early blastomeres, which, becoming freed, remain latent for a longer or shorter period, and then in response to some, as yet unknown, stimulus, resume their growth with the still inherent property of forming the structures found in the normal embryo. They are, therefore, genetically the twins of their hosts, and they may be highly complex in their development, strikingly suggesting the normal embryo, or very simple and giving very little suggestion of their origin. Gradations between the two extremes can be traced. Among the tissues found in these tumors, ectodermal structures are often prominent, and wherever teratomata occur chorionepithelioma may also occur, though absent in a majority of cases. All the ectodermal structures are of equal significance and probably assume a

special *Anlage* of fetal membranes to account for the presence of chorionectoderm. A special significance, however, must be accorded to the chorionectoderm in teratomata, like that accorded to a special tissue, such as skin or brain substance, because in most of the recorded cases it shows all the characteristics of the trophoblast of pregnancy, not only morphological (the three types of cell forms—Langhan's cells, syncytium, chorionic wandering cells—absence of vessels, etc.) but also physiological (vaso-destruction, fibrin formation, glycogen production). As in the growths following pregnancy, the chorionectoderm of teratoid tumors also assumes atypical forms, rendering their recognition difficult, and perhaps in some cases impossible. These atypical forms may present tissue similar to the so-called atypical form of Marchand, or, as the result of an excess of Langhan's cells, a more diffuse alveolar carcinomatous, papillary, cystic, or perithelial arrangement may be seen. Their true nature may be discovered by tracing a direct continuity with typical structures or a gradual but unbroken transition between the two. Frank thinks that the evidence of the nature of these growths is sufficiently established, the arguments of certain authors to the contrary notwithstanding. A bibliography of 95 titles is appended to the paper, and excellent illustrations show the microscopic structure.

Antigonococcus Serum.—J. C. Torrey gives a preliminary report of good results in the treatment of gonorrheal rheumatism with an antigonococcus serum made by the inoculation of large rabbits with cultures from an acute, untreated case of gonorrhea. The best serums were obtained by inoculations at intervals of five or six days with cultures from six to fifteen days old. The rabbits were always inoculated intraperitoneally. While he thinks that the most important factor in the good results obtained with the serum is its bactericidal action, he is inclined to believe that there is also an antitoxic action. Experiments with guinea-pigs seemed to indicate this, and clinical evidence also pointed the same way. In some of the cases of gonorrheal rheumatism treated with the serum there was a decrease of pain in the joints within twenty-four hours after the first administration, and this seems most reasonably explained by a neutralization of some of the gonotoxin. Mainly, however, the serum acts, in his opinion, by destroying the bacteria. It seems possible, he says, that it supplies enough immune bodies to dispose of the comparatively few gonococci in the chronic forms of the disease, though not enough to bring about the destruction of the great number of gonococci that are present in the urethra in acute gonorrhea. Experimental evidence fully to substantiate this theory is yet lacking. The serum, however, has been found to contain both precipitins and agglutinins for the gonococcus.

Antigonococcus Serum in Gonorrheal Rheumatism.—J. Rogers reports a number of cases successfully treated by the antigonococcus serum made by John Tory. The ordinary treatment is notoriously unsatisfactory, and while the serumtherapy has its limitations like all others, it appears to be a real benefit in these cases. It should be remembered, however, that it has little or no effect on existing urethritis, and so long as any traces of this persist there is danger of a recrudescence of arthritic symptoms. He calls attention to some of the difficulties of diagnosis, especially in women, in whom it is often undetected, and states that the use of the serum may be of value, as it will relieve the pain in a few days if the patient is gonorrheal. The possibility of a complication by another infection must of course be considered, but most joint and serous membrane affections occurring in the course of a gonorrhea can usually be attributed to the gonococcus. In any suspicious case he advises the injection of from 20 to 60 minims every day or every other day, beginning as soon as possible after the arthritic symptoms appear and continuing as long as the pain and disability last. Aside from an occasional erythema, he has observed absolutely no ill effects. The earlier the disease is recognized and the treatment commenced the better of course are the results.

Sodium Aurate.—F. H. Verhoeff believes that he has found an agent combining effective germicidal power with lack of toxicity to the tissues in sodium aurate, which is prepared by cautiously adding sufficient of a 5 per cent. solution of sodium hydrate to produce a faintly alkaline reaction with 15 grains of commercial gold chloride dissolved in 50 c.c. of distilled water. To this is then quickly added 100 c.c. of a 1 per cent. boric acid solution and the whole thoroughly shaken. The total volume should now be made up to 200 c.c. with physiological saline solution, filtered and kept in a glass stoppered bottle. The final solution should have a faintly acid reaction. When prepared as above directed this solution, in strength of 0.5 per cent. gold chloride may be repeatedly dropped into the conjunctival sac without causing irritation or hyperemia. Tests of its bactericidal power showed the 0.5 per cent. solution to be more powerful than the 1 to 1,000 solution of mercuric chloride, while the apparent difference in toxicity is still more marked. Verhoeff thinks it can be safely used in the treatment of the eye and of genitourinary diseases, so far as any remote toxic effects are concerned. The effect, however, of the absorption of large quantities of the antiseptic at frequent intervals remains to be studied. The penetrating power of the fluid is shown to be great by its bactericidal power in the presence of albumin. He finds it difficult to account for this bactericidal action, but thinks it likely that it is due to the replacement of some important radicle in the bacterial protoplasm by gold, which is itself antiseptic. To explain why it kills bacteria in less than a minute while it requires hours to react with albumin, and to explain its harmlessness to tissue cells is also difficult. Lawrence J. Henderson, in a supplementary note, points out that it gives up gold when shaken up with neutral olive oil, and that it completely coagulates albumin when reduced in its presence by ferrous sulphate or other substances. The first of these facts is significant since the lipoids of the cell wall have much the same solvent action as oil, thus explaining the penetration of the cell by a simple physical mechanism. The second fact suggests the probability that during the reduction of the gold that colors the killed bacteria, the cellular proteids are coagulated and the organism killed.

The Lancet, January 13, 1906.

Recurring Epistaxis with Multiple Telangiectases of the Skin.—The case referred to by C. O. Hawthorne was that of a woman of forty-nine, the mother of seven children. Since her first pregnancy she had been aware of the presence of red spots on her face and also on several of the finger tips of her right hand, and from one of the latter, situated just under the free edge of the nail, bleeding, presumably as a result of slight injury, had often occurred. The woman's face showed a number of bright red telangiectases scattered over both cheeks and a few were also seen on the fingers of the right hand; none were recognized elsewhere, but as the woman came to the hospital merely as a friend of one of the patients and objected to further examination, the condition of the nasal and other mucous membranes could not be ascertained. In answer to inquiries bearing on her personal history, she volunteered the remark that since childhood she had suffered from repeated attacks of "bleeding at the nose," and that on one occasion it had been necessary to plug the nostrils. Her father, also, and a sister were, so she said, troubled in the same fashion, and each of these, as well as her eldest daughter, had "spots" which she recognized as similar to those present on her own face. Further, every one of her own children had had more or less numerous attacks of epistaxis.

Sciatica of Abdominal Origin.—Two histories illustrating this mode of origin of sciatica are contributed by F. W. Forbes. Case 1, illustrating what may be called a true sensory physiological reflex nervous response of one spinal segment to peripheral irritation existing in the area supplied by another adjacent spinal segment, was that of a woman who had complained of constant pain in the tenth dorsal area with sciatica. She had had also menorrhagia and profuse leucorrheal discharge. A small papilloma was discovered in the cervix, with accompanying erosion and and ill-defined resistance in the left pelvis. The latter was found later to be a small central cyst of the ovary. Removal of the papilloma, together with a wedgeshaped portion of the cervix, and later of the cyst, led to a complete cessation of all the nervous symptoms. Case 2 was that of a woman of forty-seven years, with metrorrhagia and pains shooting down both legs. In this case also a tumor was discovered in the cervix. There was in addition a pouching out of the bladder on both sides of the tumor. The loss of blood had been very great. It was deemed advisable to remove the entire uterus, which was done, but the adhesions in the pelvis rendered the task a long and difficult one. The patient's previous condition and the necessary severity of the operation proved too great a strain for the patient, and she survived but a short time. The specimen proved to be a large myoma of the anterior lip of the cervix.

Wright's Method of Treating Tuberculosis.—Watson Cheyne refers to Wright's theory that the mode in which the body defends itself against bacteric invasion is by the development in the blood serum of substances termed opsonins, each bacterium leading to the development of its special opsonin, which, coming in contact with the living bacteria, weaken them and enable the phagocytes to complete their destruction. Apparently the body has no other means of defending itself, and the only way of aiding recovery in cases of tuberculosis, for example, is to try to increase the opsonic power in the blood. This is done by introducing minute quantities of dead bacteria of the same kind as those invading the body, and, securing that the blood serum comes in contact with the invading organisms.

The end, therefore, to be striven for is to increase the "opsonic index" of the blood. Cheyne regards the expression of this result as dependent largely on the personal equation, and as devoid of necessary accuracy. He refers to the good effect of abdominal section in tuberculosis of the peritoneum. He was at first inclined to ascribe this to the postoperative pouring out of serum containing antibacterial substances, which interfered with the vitality of the bacilli, but he is by no means satisfied with this explanation. He doubts whether in opsonins and phagocytes we have the whole defensive armamentarium of the body against the tubercle bacillus. There are probably many other factors, especially local ones, which are of equal and perhaps greater importance. He is somewhat surprised that Koch's tuberculin was so quickly thrown aside, feeling that continued investigation would have soon led to the discovery of means for overcoming the objections to its free employment. He believes that the use of this remedy should be continued. In general, his position is that it is a most valuable adjunct to our treatment, but he is not prepared to throw aside surgical measures for certain accessible and persistent tuberculous processes. The problem of cure cannot be solved merely by keeping the opsonic index of the blood up to normal by the use of tuberculin or similar compounds. The cervical glands may be cited as a familiar illustration. If they are suppurating, they are much better removed by a radical operation. This latter should then be followed up by the tuberculin on the principles of dosage laid down by Wright. A distinct plea is made in this particular instance for a "radical" operation. Mere scraping is not radical, nor is the simple removal of those glands alone which are visibly affected. Cheyne therefore advocates an elaborate operation in cases of tuberculous glands in the neck, consisting in the removal not only of all infected glands, but of all the fat and other glands in the vicinity over an extensive area. He expresses some doubt whether tuberculin is the final and best result which will ever be obtained in the treatment of tuberculosis, since in spite of long-continued use of tuberculin and marked improvement in the patients, tubercle bacilli may still be present in the urine on one hand in cases of urinary tuberculosis, in the sputum in cases of pulmonary tuberculosis, etc., after a long period of treatment; recurrences may also take place after the sores have healed in cases of tuberculosis on the surface of the body.

The Pathology and Bacteriology of Serous and Purulent Effusions in Children.—This subject is carefully worked out by J. G. Emanuel, whose detailed statements are well worthy of examination. We can refer only to certain leading propositions. Seventy-five per cent. of empyemata in children are due to the pneumococcus. The disease may be associated with pneumonia, or occur independently of it. The author believes in the primary nature of these cases. About seventeen and one-half per cent. of empemata in children are caused by the streptococcus. The disease here may be secondary to pneumonia, especially that complicating the acute infections; to inflammatory lesions elsewhere, *e.g.* otitis media, or may arise independently. Empyema due to the staphylococcus is generally secondary to suppurations elsewhere, *e.g.* infective periostitis. Empyema in children is due, some say in twenty-five per cent. of cases to the tubercle bacillus. It is rare, however, to find the organism in the effusions. All observers are agreed that a pneumococcal is mild in comparison with a streptococcal or tuberculous empyema. It must, however, be remembered that although the empyema is proved bacteriologically to be pneumococcal, it may in reality be complicating a pulmonary tuberculosis or even a sarcoma of the lung. Again, many streptococcal empyemata run a mild course. Considering pneumococcal apart from other empyemata, the author would make three degrees of virulence: (1) There is a mild variety, in which the pneumococcus remains localized to the pleural cavity. This is the case with the uncomplicated empyema. (2) There is a more severe variety, in which the pneumococcus spreads from the pleural cavity, via the lymphatics, and gives rise by direct extension to pericarditis, peritonitis, or to empyema of the opposite side. This class includes those cases described under the term polyserositis or polyorromenitis, when they are due to the pneumococcoccus and when they begin in the pleural cavity. (3) Finally, there is a very severe variety in which the pneumococcus gains access to the blood stream and gives rise by metastatic infection to such complications as meningitis, cerebral abscess, endocarditis, subcutaneous abscess, and purulent arthritis. In this way arises pneumococcal septicemia as a result of pneumococcal infection of a pleural cavity. In many cases of pneumococcal septicemia and empyema occurs which is only the expression of a localization of a general sepsis.

British Medical Journal, January 13, 1906.

A Rapid Cure for Lumbago.—G. H. Kenyon has employed for many years the local application of tartar emetic, using the B. P. ointment twice a day until the pustules characteristic of antimony make their appearance. By this time the pain is greatly relieved if not quite gone, and the patient is practically well. Along with this local treatment it is advisable to administer a saline aperient mixture containing sodium salicylate. The number of applications of the ointment required depends greatly on the thoroughness with which it is rubbed in. If this is well done, one or two applications are usually sufficient. It is prudent to warn the patient not to continue having the ointment rubbed in longer than necessary to relieve the pain, or after a fair crop of pustules have come out, as this makes the skin unnecessarily sore and ulcerated.

Food Poisoning and Coma.—The history of a case of coma following a hearty supper of fish, meat, wine, and ice cream, is given by A. D. Kennard. His patient was a waiter, aged twenty-two years. When first seen he had been all night in a state of coma with stertor, absence of all reflexes, contracted pupils, weak and rapid pulse, normal temperature, and distended bladder. The symptoms had come on rather suddenly about half an hour after eating. He was catheterized and purged. In about four hours he vomited freely and his reflexes gradually returned. A mild bronchopneumonia appeared next day at both bases, but the patient was well in ten days.

Functions of the Omentum.—A series of drawings with explanatory remarks is presented by R. Morison, who styles this structure the "abdominal policeman," and declares that it travels about in the abdomen with considerable rapidity and is attracted to localities in which lesions are occurring. Normally it forms a protecting pad for the small bowel. It may play a conservative rôle in both femoral and inguinal hernia by blocking the hernial openings firmly. It has been observed guarding a suppurating gland in the mesentery of the small gut, may occlude a perforation of the diaphragm, isolate a suppurating gall-bladder, and isolate an appendix in either the flank, iliac fossa, or pelvis. It has been found guarding a malignant ulcer of the rectum, of the sigmoid flexure of the colon, and of the colon itself. It has been observed to surround an injured piece of small intestine, to isolate pelvic tumors (degenerating myoma, ovarian cyst, ectopic gestation, pyosalpinx, etc.), and to seal an ulcer of both the stomach and duodenum. It seems to possess an especial capacity for the formation of new vessels. Morison likens the movements of the omentum in all of the above conditions to that of a jelly fish, claiming that its alternating position is due to more than mere mechanical causes.

The Reality of Enterospasm and Its Mimicry of Appendicitis.—H. P. Hawkins thinks that at the present time many an innocent appendix is excised. The great subject of functional disorders of the intestines has never been fully studied, and many cases of abdominal pain referred to the appendix are due to either enteralgia, mucous colic, or enterospasm. He presents notes of 35 patients whose sole trouble was some degree of abdominal pain or discomfort. Some of them may have been of a spastic nature. In six the appendix had been previously removed without relief to the symptoms. The author's main ideas are embraced in the following propositions: (1) It is not uncommon for men and women in equal proportions to begin in early adult life to suffer from abdominal pain. (2) From the absence of all evidence of organic disease and the long duration of many of the cases, it is unlikely that there is any structural change in the intestine or elsewhere. (3) Such patients are neurotic or neurasthenic, and the abdominal trouble varies directly with the mental state. (4) The pain may occur in short, sharp attacks; or may last for months at a time as a pain or discomfort. (5) Whether it is short and sharp, or long and wearing, the pain is usually seated in the right or left iliac fossa or the immediate neighborhood. (6) In both situations the pain may lead to the idea that more serious disease is present, as affecting chiefly the appendix, and to a less extent the sigmoid flexure.

Berliner klinische Wochenschrift, January 8, 1906.

The Apparent Anticomplementary Action of Precipitating Sera in the Animal Body.—Pfeiffer and Moreschi describe intricate observations on the actions of precipitating sera which led them to the following conclusions: Specific precipitating sera when brought in contact with their respective precipitogenous substances even in the animal body manifest a pronounced antibacteriolytic action through fixation of the complement. The effective agent is the precipitate, which either forces the complement to combine with it or destroys it. In this phenomenon the quantitative relationship between the precipitating serum and the preciptogen is of importance. The optimun of antibacteriolytic action coincides with the optimun of precipitation. This anticomplementary action of the precipitate may simulate the presence of antiamboceptors, and further investigations must show to what degree the former studies on antiamboceptors are open to criticism on this ground.

Experimental Observations on the Effect of Mineral Waters on the Secretory Function of the Stomach.—Bickel was able to duplicate on a human being the laboratory experiments ordinarily performed on dogs having a Pawlow fistula. The patient was a well nourished young woman of 23 years, without gastric disease. In consequence of poisoning by lye she had eight years previously acquired an almost complete stricture of the esophagus for which at that time a gastrostomy was performed. Recently for therapeutic purposes an esophagotomy was done; the lower end of the tube was buried and the upper end brought out of the wound in the neck, forming a permanent fistula. The author, with her consent, took advantage of this physical conformation for the purpose of determining the effect on gastric secretion of the ingestion of the various mineral waters commonly in use. It was found that mineral waters belonging to the acidulous, sodium chloride, and the alkaline muriatic groups certainly did not inhibit gastric secretion, and apparently were potent in increasing it. The alkaline-saline waters and the alkaline waters on the other hand did to some extent reduce the amount of gastric juice secreted. The bitter waters evoked the secretion of watery fluid but diminished the output of the specific components of gastric juice. The experiments were performed by introducing into the fasting stomach 200 c.c. of water through the fistula. A quarter of an hour later the water still remaining in the stomach was drained out and a factitious meal of meat and vegetables lasting ten minutes was given, the masticated material escaping from the fistula without reaching the stomach. The gastric juice was then collected from the stomach at intervals of five minutes.

Diagnostic Abdominal Puncture.—Salomon calls attention to the fact that diseases of the abdominal cavity have not yet been made accessible to diagnosis by means of exploratory puncture and describes an instrument intended to fulfill this purpose. It is a modification of one devised by Schmidt for injecting serum or salt solution into the abdomen before laparotomies for the purpose of reducing the risk of infection. It consists, first, of a short sharp trocar provided with a flange which prevents it from penetrating deeper than just through the skin. After the integument has been pierced by this a blunt pointed cannula is pushed through the muscle and peritoneum, which is usually accomplished without difficulty. The blunt cannula is provided with a lateral opening through which it is possible to direct a small flexible catheter resembling those used for the ureter, in any desired direction, and on making suction with the syringe any exudate present is easily detected. The author in this way demonstrated the presence of fluid in a case in which on autopsy only 100 c.c. of free exudate were found in the abdomen. He recommends the method as valuable in making the differential diagnosis in instances of perforative peritonitis, ureteral or biliary colic, ectopic gestation, intussusception, fat necrosis of the pancreas, traumatic injury of the abdomen, typhoid perforation, etc. The puncture is done under morphine anesthesia.

Münchener medizinische Wochenschrift, January, 9, 1906.

The Diagnosis of Flat Foot.—Schüman mentions the various methods which have been described by different authors for the purpose of obtaining permanent impressions of the sole in cases of flat foot, and describes a procedure of his own which he says is simple and gives extremely clear records. The paper to be used is lightly coated with solution of ferric chloride diluted one half and may be kept on hand until needed for use. The patient's foot receives a thin coating of a 5 per cent. solution of potassium ferrocyanide, and he is then instructed to press it firmly on the prepared paper. The result is a very clear dark blue reproduction of the sole on a yellow background. The course of the papillary lines is readily recognizable, and the pictures obtained in this way are so full of detail that the author recommends the method for the purpose of obtaining finger records in the Bertillon system of identification.

Bier's Hyperemia in the Treatment of Eye Diseases.—Renner tested this plan of treatment in a number of different ocular affections. The congestion in these cases is evoked by the application of a rubber bandage 3 cm. wide which is placed about the neck. In order to determine whether this procedure was likely to give rise to any unpleasant subjective manifestations the author tried it on his own person a number of times, allowing the band to remain in position for from three to eight hours. No disagreeable sensations followed, though after several hours there was a feeling of pressure and tension in the ocular muscles on extreme motion of the eyeballs, slight swelling in the nasal passages, and the voice became somewhat hoarse. The conjunctiva was slightly reddened, but the functions of the eye were in no way affected, and no increase of ocular tension was produced. Examination of the fundus revealed a distinct venous hyperemia of the retina. In applying the method to patients the author confined himself to individuals less than 40 years of age, as it seemed unwise to hazard the accompanying increase of cerebral pressure in individuals of advanced years. Five cases of parenchymatous keratitis were apparently distinctly benefited by the congestion, the duration of treatment being markedly shortened. The results were less evident in several cases of serpigenous ulcer of the cornea, and in the phlyctenular and catarrhal ulcers of the cornea no improvement appeared to follow this form of treatment. Although the number of cases reported is small the author considers that the method gives sufficient promise to justify further attempts in this direction.

Further Observations on the Etiology of Syphilis.—Siegel contributes another report on his progress in the study of the *Cytorrhyctes luis* and describes previous observations by several older investigators which lead him to think that they also were working on the same parasite. A new method of staining is given by means of which the author says that successful blood preparations can be quickly made. The stain consists of methylene blue 1, borax 2.5, distilled water 100. This is allowed to act for ten minutes and the smear is then washed with water. Numerous control observations have convinced Siegel that his organisms are not artefacts or bits of degenerated cells. Twenty specimens of syphilitic blood have been examined, and in each case it was found that at the time of the initial lesion nothing suspicious was present in the blood but that numerous organisms could be discovered as soon as the exanthem appeared. Elaborate inoculation experiments on white mice and monkeys are also described. Leucocyte counts on seven monkeys uniformly showed a rather sudden rise in the number of leucocytes about the fourteenth or fifteenth day which occurred coincidently with the appearance of the eruption. A monkey inoculated with the fourth generation of the parasites obtained from syphilitic placentas and cultivated on human blood bouillon developed the usual lesions at the end of fourteen days and had cytorrhyctes in his blood.

Deutsche medizinische Wochenschrift, January 11, 1906.

The Radium Treatment of Trachoma.—Jacoby treated eight cases of trachoma and three of follicular conjunctivitis with radium. One eye in each case was treated by the ordinary methods and the other was subjected to the action of the radium. The test seemed to show that a distinctly beneficial action was exerted by the radium but its results were distinctly inferior to those attending the usual mechanical and medicamentous treatment. Although direct injury would be caused by the radium treatment only in such cases in which on account of their progressive nature active intervention is required, it is probable that its use in all cases leads to loss of time. The author suggests that whatever good effect is manifested under the influence of the radium treatment may be due to other factors, such as the hyperemia caused by the more or less protracted exposure to the air of the conjunctivæ, or the gentle message attending the application of the radium capsule to the diseased surfaces.

Subcutaneous Rupture of the Spleen.—Friedheim reports two cases of splenectomy for rupture of the spleen, followed by recovery. The first patient was a coachman 23 years old whose injury was caused by the kick of a horse. There were no symptoms pointing toward injury of the spleen so that a median incision was made which was subsequently extended along the free border of the ribs on the left side when the seat of the hemorrhage had been discovered. This patient had lost about two liters of blood or two per cent. of his body weight. The other patient was a boy four years old who had been run over; as he had several times vomited blood an injury to the stomach was assumed and the median incision made in this case also. When the spleen was found to be the injured organ the incision was extended as in the previous case. This boy had lost about three-quarters of a liter of blood or five per cent. of his body weight. In each case the abdomen was closed without drainage, although at the second operation a considerable amount of blood clot was left in the abdomen. Both patients were discharged at the end of four weeks in perfect health. In the case of the adult the blood picture had returned to the normal on the eighth day after the operation, but improvement to this degree did not follow with the little boy until about four weeks had elapsed. The author says that the latter case is of especial interest since it shows that the spleen may be removed even at an early age without leading to consequences of moment.

French and Italian Journals.

The Eggs of Intestinal Parasites.—Maurice Letulle gives a list of the most ordinary intestinal parasites. In the

order of their size, not mentioning the eggs of the tænias, he gives the following list of parasites the eggs of which are often found in human feces: trichocephalus, oxyuris vermicularis, ankylostoma duodenale, bothriocephalus, ascaris lumbricoides, and Bilharzia hæmatobia. The investigator should be familiar with the appearance of these eggs. When an egg is found in the feces, its form, color, power or reflection, its dimensions, structure, and artificial modifications (solutions) should be studied. Besides these points, its signs of vitality (contractility), and the relative numbers in the various preparations examined should be noted. The microscopic examination of the eggs contained in the feces is indispensable to the clinician. The technique is simple and the diagnosis certain.—*La Presse Médicale*, December 30, 1905.

Perivascular Lesions of Generalized Scleroderma.—Alquier and Touchard have made careful observations in their study of this disease. They believe that in an early stage of generalized scleroderma there may be observed around the small bloodvessels elongated cells of the connective tissue type and of the type of mast cells. The number of these cells seems to be in inverse ratio to the degree of sclerosis, diminishing as the disease progresses. In generalized scleroderma, it seems that the sclerosis of the connective tissue begins by a perivascular irritation. The determination of this fact added to that of early lesions in the small blood vessels, the tumefaction of the endothelium, and the thickening and degenerative lesions of the wall, seems to justify the hypothesis which considers this disease as related to a blood intoxication.—*Gazette des Hôpitaux Civils et Militaires*, December 28, 1905.

Perforation of the Stomach in the Course of Latent and Unrecognized Ulcers.—Benjamin Ball discusses a question of the greatest interest to the medical practitioner when he seeks to make clear a diagnosis upon which depends the life of the patient. It frequently happens that a patient succumbs to a perforation, when immediate intervention would have saved him from death. Ball has collected ninety-two cases of perforations in the course of gastric ulcer in nearly all of which death took place in from twenty-four to thirty-six hours. It is most important in these cases to make a rapid diagnosis and to practice surgical intervention without delay. Diagnosis is not always easy. Frequent errors in diagnosis occur as in cases of appendicitis, intestinal occlusion, poisoning, lead colic, not to mention duodenal perforations which it is almost impossible to differentiate. The physician should be convinced that an early intervention alone will save the patient. There is no comparison between the danger of a laparotomy and that of an unrecognized perforation.—*Le Bulletin Médical*, December 30, 1905.

Urinary Chlorides and Clinical Forms of Tuberculosis.—Piéry and Etienney give a report of work that has been done in Bondet's clinic. They state that elimination of chlorides in the urine undergoes numerous variations in the different clinical forms of pulmonary tuberculosis. Fibrocaseous phthisis is characterized in its periods of remission by a notable decrease in the elimination of chlorides. When caseation extends, the excretion of the chlorides increases progressively with the periods of infiltration and softening. The excretion of chlorides becomes normal or slightly increased in the stage of cicatrization of the cavity. Galloping consumption and cascous pneumonia show in the beginning a decided decrease in the elimination of chlorides; in the height of the disease the chlorides are slightly diminished and in some cases normal in amount, while at the last they are considerably decreased. The amount of urinary chlorides, however, in the course of abortive pulmonary tuberculosis is notably decreased. The retention of chlorides is still more decided in fibrous phthisis. From the point of view of prognosis, excepting the first stage of phthisis, the more serious the tuberculosis the less marked is the retention of chlorides.—*Lyon Médical*, December 31, 1905.

Acute Poisoning with Bichloride of Mercury.—Ambrogio Mori describes the symptoms of acute poisoning with bichloride of mercury in a baby, who swallowed 70 c.c. of a 3 per cent. solution of corrosive sublimate. Mucous and biliary vomiting streaked with blood occurred, the kidney function was suspended, there was a frequent pulse, asthenia and rapid collapse occurred, and death followed. The anatomical lesions were characteristic of acute mercurial poisoning. The action of the poison as a caustic was limited to the stomach, the pyloric orifice having closed, so that the material was all removed by the vomiting, and none passed into the intestine. The esophagus, pharynx, and stomach were necrotic. There were grave secondary hemorrhages in the intestines, from lesions of the endothelium of the capillaries of the villi, due to the blood dyscrasia produced by the poisoning. There was a process of steatosis in the hepatic periportal acini. There was beginning necrosis of the kidney epithelium characteristic of mercurial intoxication.—*Rivista di Clinica Pediatrica*, December, 1905.

Influence of the X-Rays on the Evolution of Silk-Worms.—H. Bordier has studied the effect of the *x*-rays on the metamorphoses of the silk-worm in its life cycle. The worms were taken on the day after birth and exposed to the rays, at a distance of 8 centimeters, for a quarter of an hour each day. They became more active than normal. The changes were retarded in the animals treated, taking 36 instead of 29 days, as in the untreated worms, and the transformations came about in an abnormal manner. Most of the chrysalides were dead, with a hemorrhage from the mouths of the worms; no wings were formed. The cells of the animals seemed to have been affected. There was less silk spun than usual.—*Annali di Elettricita Medica e Terapia, Fisica*, November, 1905.

Anemia of Parasitic Origin.—De Renzi and Caporali state that among the diseases that produce anemia we must reckon some that are produced by parasites. Of these we may distinguish two great classes: parasites of the blood itself, and intestinal worms. Those in the second class constitute a well-marked group, well known in its etiology and complex in its clinical manifestations. Among the diseases due to blood parasites the principal is malaria, and among those due to intestinal parasites is that resulting from ankylostoma duodenale. But the ankylostoma is not always directly the cause of the anemia, and ankylostomanemia must be distinguished from simple ankylostomiasis. As to the cause of the anemia in ankylostoma disease, it is believed to be not only the loss of blood consumed by the parasite, but also the intoxication resulting from toxic substances, as was demonstrated by Lussana and De Giovanni. Such toxic substances may be elaborated by the parasite, or result from the disturbances of intestinal chemical activity.—*La Riforma Medica*, December 23, 1905.

A Note on Tuberculosis.—Noir has made some very interesting studies concerning pulmonary tuberculosis as it has occurred in paupers in a corner of the old part of Paris. In the section which he has studied there are seventeen streets and two hundred and fifty-one houses. Most of these dwellings were built before the eighteenth century. Their unhygienic condition is notorious. The houses are from five to six stories high. In three-quarters of the cases each family has but one room, which they use as a work room, a kitchen, a dining-room, a bedroom, and sometimes as an infirmary. It is not a matter of surprise then that in eleven years one hundred and five persons have died of contagious diseases and seven times that number of tuberculosis. The writer concludes by demanding that these unhygienic abodes shall be destroyed and that the municipality substitute for them lodgings for workmen provided with air and light.—*La Tribune Médicale*, November 18, 1905.

Female Type of Hand in Extension or Sigmoid Carpus.—By this term R. Kingman refers to a double or S-shaped curve of the wrist and hand involving the portion of the upper extremity from the tips of the fingers to, and including, the lower ends of the radius and ulna. This S curve is made up of two parts; one being formed by flexion at the wrist where the carpus articulates with the ulna and radius, and the other by overexertion at one or more of the three finger joints (the first and second phalangeal and the metacarpophalangeal or knuckles). Viewed from above, the proximal arc of the S is convex and located at the wrist joint, while the distal arc is concave and located at one, two, or three of the phalangeal articulations. From below the reverse, of course, presents; a proximal concave joined to a distal convex arc. The sigmoid carpus may best be observed, however, in profile from the ulnar aspect of the hand, the characteristic appearance being somewhat obscured on the radial border by the thumb. This form of carpus is distinctly characteristic of the female hand, and the author gives the results of examination of a considerable number of wrists in both sexes. He refers also to changes in the wrist contour as effected by various occupations and diseased conditions. He suggests that further study and observation may show the absence of the sigmoid type in the female and its presence in the male to be of some diagnostic value in conditions of disease. He thinks that males who live, work, and think on a plane of continual high tension often exhibit the feminine form of hand.—*Medical News*.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundredth Annual Meeting, Held in Albany, January 30, 31, and February 1, 1906.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. JOSEPH D. BRYANT OF NEW YORK, IN CHAIR.

TUESDAY, JANUARY 30—FIRST DAY.

THE society was called to order by the president. Prayer was offered by the Rev. F. St. George McLean, Rector of Trinity Episcopal Church.

Address of Welcome.—Dr. JOSEPH D. BRYANT of New York said that it was with hearty realization and unalloyed pleasure that he desired all to join with him in greeting this moment's existence of the medical profession of the State of New York with glad recognition. If he was a competent judge of the meaning of the hearty cooperation that characterized the efforts of all concerned in reorganization throughout the State, and of the seeming contentment that appeared to distinguish those there assembled, then, indeed, were these feelings shared to the fullest extent by everyone coming within the influence of the sentiment dominating the reorganization. In any event, he begged to assure them that the medical profession of the country regarded this occasion as one of the most important in the history of its existence. The chastening influence of earnest contention in all fields of human conflict was often not unlike that witnessed in the common convulsions of nature; the air was made the clearer and the purer thereby, the purposes of God and man were better understood, and corresponding things were improved and established upon a better and firmer basis. The enrolled regular physicians of the State, not less than 6,500 in number, were to-day a united body of attentive medical men, laboring in common for commendable interests and beneficent causes. The medical profession of the State could now take hold with a firm, confident grasp in support of wholesome, public-spirited propositions, with full consciousness of the fact that their united desire would constitute a bulwark of moral force, not to be misjudged or indifferently considered. So long as the medical profession should contribute its part to the interests of the public good, the public servants would heed its admonitions and respect the logic of its appeals. He said that every regular physician in the State should be a member in good standing in this organization, and everyone thus enrolled should recognize the fact that he himself was as potent a factor in the affairs of the organization as was any other member. The present status of this medical body had been attained only through the extraordinary zeal and infinite patience practised by the "Joint Committee of Conference," to which some time ago the fortunes of the independent medical bodies were mutually and wisely entrusted. Much yet remained to be accomplished under the order of the court before the control of the affairs of the great body could be relegated by the *ad interim* House of Delegates to the completed organization. He expressed the hope that all who were engaged in the completion of this great work would cooperate promptly and cheerfully with those now vested by the court with the construction of the legal framework required for the purpose. He said that they had been legally informed that only the report of the Joint Committee on Conference and of the *ad interim* House of Delegates, and a resolution of continuance of power were in order. A communication from Dr. Lewis S. McMurtry, president American Medical Association, was then read, in which he congratulated them on this consummation, which had been so long desired by the profession of the United States. Since the organization formed by this union became the constituent branch of the American Medical Association, in behalf of that association he extended a cordial greeting to the society and a welcome to the council of the united profession.

Report of the Committee on Conference.—Dr. HENRY L. ELSNER read this report, which follows:

To the Medical Society of the State of New York:

Your Committee of Conference in making this, its fourth and last report, begs leave to call your attention to the following:

The object for which the Committee of Conference was appointed at the annual meeting in January, 1902, has been accomplished.

The unification of the regular profession of this State in the Medical Society of the State of New York with representation in the American Medical Association has become a fact.

The individual members of county medical societies in affiliation with the State Society by virtue of such membership now enjoy all of the advantages of membership in this State body; thus our society becomes at once the most powerful State medical organization in the United States.

It is unnecessary at this time to rehearse the sequence of events which have led to this happy result. The three preceding reports of the Committee of Conference, all published in the Transactions of the Medical Society of the State of New York during the years 1903, 1904, and 1905, give these in detail.

Your committee in its last report, after considering the legal obstacles with which the Joint Committee of Conference were confronted, suggested, on advice of counsel, in order to make the title of this body clear, without flaw or question, that at both the annual meeting held in Albany on the 31st day of January, 1905, and at a special meeting which was called in the same city on Thursday, February 2, 1905, in accordance with the Constitution and By-Laws, this society approve and adopt the proposed agreement of the Joint Committee of Conference.

Your committee recommended at these meetings that the resolution adopted at the preceding annual meeting, subscribing to the agreement and adopting the Constitution and By-Laws as printed in the Transactions of this society for 1904 be rescinded, and that following this action at both these meetings the society again subscribe to the agreement and readopt the Constitution and By-Laws contained in the report of your Committee of Conference at the annual meeting of the society in 1904, and published in full in the Transactions of the Medical Society of the State of New York for the same year.

It was suggested by the Committee of Conference in its last report that as soon as the New York State Medical Association shall have taken similar action, the Medical Society of the State of New York, through its committee, shall be reorganized in accordance with the agreement, Constitution and By-Laws unanimously adopted at the annual meeting in 1904.

On the receipt of the report of this committee, for the purpose of conforming to legal requirements, it was moved and carried that the following resolution adopted at the annual meeting in 1904 be rescinded:

"Resolved, That the report of the Joint Committee of Conference be accepted, and that the proposed agreement for the consolidation of the Medical Society of the State of New York and the New York State Medical Association be and the same is hereby approved, and the president of the society is hereby authorized and directed to execute the same in the name and behalf of the society, and the secretary is hereby authorized and directed to affix the corporate seal thereto."

The following was then unanimously adopted:

Resolved, That the report of the Joint Committee of Conference be accepted, and that the proposed agreement (including the Constitution and By-Laws), for the consolidation of the Medical Society of the State of New York and the New York State Medical Association, a copy of which appeared in the Transactions of the Medical Society of the

State of New York for 1904, page 22, and is also appended to the report of the Committee of Conference, and made a part of such report, made on the 31st day of January, 1905, to this society, be and the same is hereby approved, and the president of the society is hereby authorized and directed to execute the same in the name and behalf of the society, and the secretary is hereby authorized and directed to affix the corporate seal thereunto; and be it further

Resolved, That the Committee of the Society heretofore appointed for the purpose of bringing about the consolidation, namely, Drs. Henry L. Elsner, Abraham Jacobi, Albert VanderVeer, George Ryerson Fowler and Frank Van Fleet, be and they are hereby continued as such committee, with full power and authority to do whatever may be necessary to carry the agreement into effect.

At the special meeting of the Medical Society of the State of New York, held in the city of Albany, February 2, 1905, the chairman of the Committee of Conference presented the report of that committee with the agreement which was presented at the annual meeting on the morning of January 31, 1905, which report was unanimously accepted. Whereupon, by unanimous vote, a resolution was adopted accepting the report of the Joint Committee of Conference and the proposed agreement for the consolidation of the Medical Society of the State of New York and the New York State Medical Association, including the Constitution and By-Laws, and the president of the society was authorized and directed by such resolution to execute the same in the name and behalf of the society, and the secretary was authorized and directed to affix the corporate seal thereunto. It was further

Resolved, That the committee of the society mentioned in the resolution above quoted be appointed for the purpose of bringing about the consolidation, and said committee was continued with full power and authority to do whatever might be necessary to carry the agreement into effect.

By this action of the Medical Society of the State of New York it became possible as soon as the New York State Medical Association took similar action, to unify the regular profession of this State.

At the twenty-second annual meeting of the New York State Medical Association, held at the New York Academy of Medicine, in the city of New York, on Tuesday, October 17, 1905, a resolution was adopted in which the association subscribed to the agreement of the Joint Committee of Conference, and appointed a committee consisting of Drs. E. Elliot Harris, Julius C. Bierwirth, Alexander Lambert, Parker Syms, and Wisner R. Townsend to carry out the purposes of said agreement, and with full and absolute power to take any and all legal steps necessary in the premises in the place of the said New York State Medical Association, as may be necessary to complete the consolidation of the New York State Medical Association and the Medical Society of the State of New York.

The action of both State bodies made it possible in accordance with an "Act to authorize the consolidation of the Medical Society of the State of New York and the New York State Medical Association" (Chapter I of Laws of 1904), which was duly introduced into the Senate and Assembly of the State, promptly passed and signed by the Governor on the 21st day of January, 1904, to petition the Supreme Court for an order consolidating the corporations. Said Act provided that when the order is made and duly entered the corporations, parties to the agreement shall be one corporation under the name, "Medical Society of the State of New York," which shall *not* be deemed to be a new corporation, but to be a continuation of the Medical Society of the State of New York, incorporated in 1806. It was provided that a certified copy of said order shall be filed in the office of the Secretary of State.

At the meeting of the Joint Committee of Conference, held in the city of New York, on October 20, 1905, the chairman of the Committee of Conference of the Medical Society of the State of New York was authorized to engage counsel for the purpose of presenting the petition to the Supreme Court for an order consolidating the corporations. Mr. Frederick Collin, of Elmira, who had already served the Conference Committee of the Medical Society of the State of New York, was engaged for that purpose, and on the 9th of December, 1905, Mr. Collin appeared before Mr. Justice John M. Davy in the city of Rochester, N. Y., and made such application pursuant to the Act above mentioned, known as Chapter I of Laws of 1904. Such order was promptly granted by the learned Justice, and a certified copy of said order has been filed in the office of the Secretary of State. All property belonging to the corporations so consolidated has been vested in the said Medical Society of the State of New York.

Pursuant to Section 1 of the agreement executed by the Medical Society of the State of New York and the New York State Medical Association, which agreement was made a part of the order of amalgamation entered on the 9th day of December, 1905, by Mr. Justice John M. Davy, a Justice of the Supreme Court, the *ad interim* officers, Chairmen of Standing Committees, House of Delegates, Council of the Medical Society of the State of New York created by such order of consolidation, must of necessity be authorized, directed and empowered to continue to exercise the respective powers and authority for the organization of the members of the consolidated corporation and the management of its affairs pursuant to the Constitution and By-Laws of the Medical Society of the State of New York until the annual meeting of the Medical Society of the State of New York, which shall take place on the last Tuesday of January, 1907. Your Committee of Conference, therefore, recommends that action be taken by the Medical Society of the State of New York at this, its annual meeting, in accordance with such agreement and order.

The Committee of Conference, in making its final report, wishes to express its appreciation of the encouragement and support received from the individual members included in the unified profession as represented at this time in the Medical Society of the State of New York. Its labors have been materially lightened by such assistance. Without it unification would have been longer postponed.

The committee wishes still further to express to the members of the Joint Committee of Conference who represented the New York State Medical Association its appreciation of the uniform courtesy and consideration extended, which made it possible for the committee to act harmoniously with a single object in view, and that, the upbuilding of a model State Medical Society.

The committee has at no time been unmindful of the valuable assistance cheerfully rendered by those who have served as presidents of the State Society since its appointment, and wishes at this time to make public acknowledgment of its appreciation of their efforts.

On this centennial occasion your committee feels justified in congratulating the society upon the unification of the State profession without interference with the life or activities of our time-honored society.

The committee feels that the future success of the State Society must largely depend upon the efforts of its individual members and the earnestness with which the many advantages of this body shall be presented to the profession of the State, and would therefore suggest in conclusion that concerted effort be made which shall have for its object the upbuilding of the county societies, their stimulation to greater scientific activity, and the addition to these of the many worthy members of our profession who have never understood the advantages of membership, now greater than ever before, because of a union which shall continue for all time to strengthen the profession and extend its influence with the public and the State.

Respectfully submitted,

HENRY L. ELSNER, Chairman,
A. JACOBI,
A. VANDER VEER,
GEO. RYERSON FOWLER,
FRANK VAN FLEET,
Committee.

Lucien Howe Prize.—Dr. F. C. Curtis read a communication from Dr. Lucien Howe in which he expressed the wish that the society receive from him a gift of $1,500, the interest on which was to be devoted to the bestowing of a prize, either of money or in the form of a suitable medal, for original contributions to our knowledge in some branch of surgery, preferably ophthalmology. It was not necessary that the competitor should be a member of the society.

Dr. A. Jacobi moved that the money be accepted and that the thanks of the society be tendered the doctor; also that the prize be called the Lucien Howe prize. This was seconded and unanimously carried.

Dr. Louis M. McMurtry, president of the American Medical Association, was then introduced and said that in 1847 a committee was appointed in New York State to call together medical men to unite and confer together as to the best methods of organization with a view of advancing the interests of the medical profession, their education, and other matters that concerned the profession, and this was in truth the foundation of the American Medical Association. The Medical Society of the State of New York was the parent body of the largest medical organization that existed in the world. The relationship was a tender and a strong one, and filled with good feeling and gallant spirit, the society now came forward and took charge of the child that had outgrown it. The Medical Society of the State of New York came again into its own, returned to the child which it fostered, and now took its place as the bright star in the constellation of the states.

The Science and Art of Fitting Glasses.—Dr. A. Edward Davis of New York read this paper, first giving a brief history of the subject, the discovery of spectacles in the thirteenth century by Salvinus Amatus, and the use of spherical glasses for the correction of old sight or presbyopia until the middle of the nineteenth century. Thomas Young discovered astigmatism in his own eye in 1801 and the astronomer Airy fitted his own astigmatism in 1837, the first cylindrical glasses to be worn. In 1851 Helmoltz discovered the ophthalmoscope, and it was then that the interior of the eye could be examined and the true nature of errors of refraction be recognized and classified, as well as the pathological changes in the interior of the eye discovered. In 1864 Donder's classical work on refraction and accommodation of the eye appeared and was the solid foundation for this branch of ophthalmology. The different tests employed in the fitting of glasses were described, as employed to-day, and the use and non-use of cyclopegics discussed. Also the matter of properly ground and adjusted glasses.

Dr. Francis Valk of New York objected to the title of the paper, and looked upon the fitting of glasses as part of one's armamentarium, being only one of the means by which an end was accomplished, in much the same way that one prescribed a dose of medicine.

Dr. A. G. Bennett of Buffalo advocated the use of cyclopegics and said he would not know exactly what he was dealing with if he did not use them, especially in estimating the errors in astigmatism. After homatropine he used eserine in order to overcome the blurring that followed.

Dr. Connor of Detroit said that he never had known a patient to complain of bad results after using homatropine. In using mydriadics he believed that strong solutions were required and he had never seen untoward results follow. He did not think that anybody had any right to say what ought to be done unless he was able to grasp the totality of the patient. No hard-and-fast rules could be laid down, but the patient should be studied as an individual. He had found good results from the use of the retinoscope.

The Immediate and Early Treatment of Ocular Injuries.—Dr. Alvin A. Hubbell of Buffalo read this paper and emphasized the following in conclusion and in résumé: 1. Injuries of the eyelids and other ocular appendages seldom affected vision, infection rarely followed, wounds healed rapidly, and they were to be treated simply in accordance with the ordinary rules of surgery. This treatment might be carried out by any intelligent practitioner. 2. Superficial injuries of the cornea were more important. Infection frequently took place, and then there was danger of a suppurative process, which might extend throughout the cornea or even involve the whole eyeball. The early treatment, while somewhat technical, might be conducted by the physician, and consisted in removing foreign bodies and using applications to prevent infection. 3. Penetrating wounds of the eyeball should always be approached with more or less concern. If not already infected at the time of the injury they easily became infected afterward. Moreover, a foreign body might have been driven into the eye, which not only carried infection with it, but which in itself became almost a certain cause of destructive inflammation. 4. In every punctured wound of the eyeball, inflicted by a small, unseen object, there should always be a suspicion of the introduction of a foreign body. The diagnosis was often difficult, and required special appliances and experience. The removal of a foreign body from the interior of the eye was almost imperative to its salvation. Here, too, special equipment and special skill were demanded. 5. Infection, by whatever means it might have been introduced, was the agent which destroyed the injured eye, both by suppurative processes and by non-suppurative uveitis. 6. In non-suppurative traumatic uvetis the infection seemed to be of a specific kind, and was transmissible to the uninjured eye, producing there a sympathetic uveitis which was also destructive in its course. 7. Sympathetic inflammation did not develop until at least two weeks after the injury of the first eye. In the absence of a foreign body, or after its removal, the immediate treatment of a perforating wound consisted in sterilizing the eye and its surroundings, freeing the wound of all incarcerated tissues, and closing it as perfectly as possible, or touching the opening with carbolic acid. Subsequently, sterilization should be kept up as effectually as the circumstances would permit. 8. Infection should be combated by intraocular disinfectants and rendered dormant by the persistent and methodical application of cold over the eye. 9. An eye that was hopelessly lost at the time of the injury should at once be excised, the operation for which might be performed by any informed practitioner. 10. When an eye was affected with active traumatic uveitis it should be enucleated within two weeks from the time of the injury, unless the eye had useful vision or might be given useful vision by some operative measure. 11. In wounds of the eyeball of all varieties delays were dangerous, and if there was the slightest possibility of a foreign body being lodged within the eye, or if infection had begun, the dangers to sight were so great that the services of a specialist should always be secured if possible.

Typhoid Fever, with Special Reference to Its Incubation Period and Reincubation Cycles.—Dr. Luzerne Coville of Ithaca read this paper. After quoting largely from medical literature regarding the incubation periods of this disease, he said that enteroclysis, when consistently carried out, defeated the toxin accumulation in the body as did no other single treatment. The bacillus coli communis was a close competitor in the intestinal condition of typhoid patients. The colon bacillus regularly attacked the sugars and rapidly produced gas. Thus the milk diet of typhoid patients was bad because, through the contained lactose, a peculiar aggravation of the typhoid growth and virulence and an increase of necrosis toxins in the intestinal tract resulted. He believed that equally bad was the bath treatment, in that it used up the patient's energies. In his experience with the Ithaca epidemic in 1903 about one-quarter of the cases ran only short, mild temperatures of 99° to 99.4° for a day or two and then became subnormal. In another one-quarter of the cases the fever began and continued from three to ten days; these patients slowly recovered, and sometimes later had severe typhoid fever. Another one-quarter of the cases were typical of the disease. He believed the usual primary incubation period to be pretty uniformly twelve days.

Dr. Kinnicutt of New York said he did not know upon what the reader of the paper based his opinion regarding the use of the cold bath, whether laboratory experience or clinical observation. He believed the cold water treatment was an admirable one, and had aided in reducing the mortality greatly, at least 3 per cent. Formerly the mortality was 10 per cent. or 11 per cent., and now it had been reduced by means of the cold water treatment to 6 per cent., or 7 per cent.

Dr. DeLancey Rochester of Buffalo said that if one watched the cases closely enough he would not find recurrences so often, but complications, such as of the gall-bladder, of the appendix, of the ear, or of the lungs. He emphasized the importance of the Brandt method of treatment, and said that this meant, not sponging, but tubbing, reducing the temperature of the water from 85° to 65°. Enteroclysis with decinormal salt solution he was not an advocate of, because it carried with it toxic material from the bowels. It would be better if the bowels were washed out with boric acid solution or ichthyol.

Dr. Styles of Owego spoke of factors which influenced the period of incubation, such as the virulence of the poison, the condition of the soil, the natural resistance of the patient, and the environment. He said it was a mistake to treat the typhoid fever; one should treat the individual, meeting the indications as they arose, contributing to the comfort of the patient as best one could.

Centennial Exercises.—These exercises were held in the evening in Emmanuel Baptist Church, before a very large audience.

Address of the President.—Dr. Joseph D. Bryant of New York, on behalf of the Medical Society of the State of New York, welcomed all on this joyous occasion and invited all to participate in the centennial exercises. One hundred years ago witnessed the birth of the Medical Society of the State of New York. During this time the means of human intercourse had multiplied in number and efficiency to a startling degree. The ten-mile passenger railroad from Stockton to Darlington, England, of 1825, and the seventeen-mile one from Albany to Schnectady of 1830, with its daily passenger list of 387, were mere traces, primitive traces of those of the present time. To-day the world had quite 440,000 miles of railroad, of which nearly 214,000 were in the United States, and conveying in the United States alone, over 716,000,000 passengers. The telegraph, the telephone, and wireless telegraphy were all of such modern invention, utility, and thrift that no special statement regarding them was required. The loom, the printing press, the reaper, and many other labor-saving, civilizing, and wealth-producing instrumentalities were of common knowledge and in constant use everywhere. The onward march of freedom during this century had kept pace with the advance of general human intelligence and human sympathy. Great Britain in 1843 emancipated 12,000,000 slaves. France, in 1848, Sweden in 1846-7, Denmark in 1848, Netherlands in 1862, abolished slavery. In 1861 Russia emancipated about 22,000,000 serfs. In 1860 there were nearly 4,000,000 slaves in the United States, but in January, 1863, slavery was abolished by the proclamation of Abraham Lincoln. The immense contributions to the healing art during this centennial period were no less astonishing and in the fore-rank was vaccination and close at hand anesthesia; then too, the twin marvels, antisepsis and asepsis. Antitoxin, the *x*-ray, the discovery of the tubercle bacillus, and the kinship between the mosquito and the yellow fever plague of commerce and of malarial torment, were most beneficent contributions to the relief of human suffering. Medical and surgical afflictions which hitherto yielded only to merciless fate now yielded with seeming ease to the measures of modern medicine. Life's expectation, he said, had been remarkably advanced during the last one hundred years. The expectations of life had increased in New York City since 1886, from a little more than 25 to quite 41 years, representing an equivalent in saving of 28,000 lives annually. In the 17th and 18th centuries the average death rate of the civilized world was about 50 per 1,000. In London, from 1628 to 1635 (in the absence of pestilence) the average death rate was 50 per 1,000. In 1902 in London the average death rate was a little more than 17 per 1,000. The broadening of the horizon of human thought and of human understanding, the product of enlarged human contact and interests, was rapidly leveling the barriers raised by sectional prejudices and doctrinal differences throughout the world, banishing the discords in professional strife that characterized the time of the birth of this organization but now rarely ever witnessed under any circumstances.

Hon. Charles H. Gaus, Mayor of Albany, welcomed the Society in behalf of the city.

Lieut.-Gov. Bruce, in the absence of Hon. Frank W. Higgins, Governor of the State of New York, addressed the Society, taking as his text, The Empire State.

Hon. St. Clair McKelway of Brooklyn, said that the State was urged to recognize some new division or branch of alleged medical theory or practice, in addition to those already recognized, nearly every year. Whether the State would do that or not was not for them or for him to determine. But it was for them, as citizens of the State, to consider, and by their consideration to help the State to a right conclusion. He emphasized the fact that the State would not lower the standard of primary medical education. The State would insist upon the literary and clinical requirements of that instruction, and upon the final examination of the students for that instruction, under State auspices within the subjects to which each school was addicted and limited. He called attention to the fact that the Board of Regents simply received orders from the Legislature, and that the Board was limited by those orders. This State insisted on prescribing primary standards in its own schools, and monopolized the control of intermediate education through its own Boards. After doing both it reserved to itself the licensure of medical, legal, dental, pharmaceutical, and other learned practitioners. It then created the demand that it should eventually provide and control the institutions themselves, whose human product it vised, examined, and licensed.

Centennial Exercises.—These furthe exercises' were held in Odd Fellows' Hall.

Oration on Medicine.—Dr. S. B. Ward of Albany delivered this address on the History of Medicine. In a general way he divided the century into four periods of twenty-five years each, and stated what progress was made in each. He pointed out that the real advance of medicine as a science began when the efforts to evolve new theories, and make facts accord with them, gave way to the scientific method of observing facts and generalizing from them. Among the characteristic conditions were mentioned the general introduction of vaccination which, of course, began just before the period of which they were treating; the discovery and perfection of auscultation, percussion, and the use of the stethoscope; the introduction of the clinical thermometer and of the sphygmograph; and especially the discovery and proof of the bacterial origin of disease, with the consequences that flowed from it in the way of treatment, and more particularly of prevention. The advance in medical education and the great assistance which the practitioner received from trained nurses, and the importance of laboratory examinations of the blood, sputum, and excretion, were also dwelt upon.

Oration on Sanitation.—Dr. Hermann M. Biggs of New York delivered this oration. He said that when one came to analyze the causes which had contributed to the extraordinary decrease in the death rates during the last four decades it was noted that they were very numerous and varied in character. During the earlier periods the improvement in health of the inhabitants of

large cities was to a great extent due to improvements in the general sanitary conditions and related to such problems as the provision of a pure and adequate water supply, the installation of systems of sewerage and improvements in the drainage, ventilation, and character of the habitations, paving the streets, abolition or restriction of nuisances, supervision of supplies of milk and food, including inspection of slaughter houses, the exclusion of epidemic diseases through quarantine, increasing efficacy in vaccination, the prevention of overcrowding, and other similar general measures. He then considered some of the factors by which reduction in mortality had been brought out. The most important development in preventative medicine in the early half of the century related to smallpox and the discovery of vaccination by Jenner. As a result of systematic vaccination and revaccination smallpox had become an insignificant cause of death in all well-regulated communities. In 1902 more than 800,000 vaccinations were made in New York City by the medical inspectors. Since the discovery of the etiological factor of cholera they had learned how to guard against this disease. It could not be doubted that the prophylactic measures based on this knowledge had kept Europe free from cholera in recent years. The outlook seemed hopeful that during the present century this disease would be controlled by preventative inoculations. The very large reduction in the death rate from surgical infectious diseases had been a material factor in the reduction of the general death rate. An extraordinary reduction in the death rate from diphtheria during the last ten years had occurred from the use of antitoxin, and in New York City this reduction had amounted to about 78 per cent.; that was, the death rate from diphtheria in the boroughs of Manhattan and the Bronx during 1905 was only twenty-two per cent. of what it was in these boroughs in 1894, which was the last year before the introduction of antitoxin. The annual saving of life in these boroughs alone amounted to nearly 3,000. The most important group of diseases as the cause of infantile mortality was the diarrheal and in the early seventies the death rate from this group of diseases alone varied between 40 to 60 per ten thousand of the population. In 1881 this had fallen to 36, and since that time the decrease had been continuous, until the last five years it had varied from 13 to 15. This decrease was due to a variety of causes, the most important of which was the improvement in the character of the milk supply of the city. In two or three classes of diseases there had been a steady increase in the death rates during the last forty years, especially in the combined death rates from diseases of the kidney and diseases of the heart. In the last forty years, since 1866, the death rate from these causes had increased about 12 per 10,000 of the population. A well-devised system of prophylaxis based upon scientific investigation of disease provided scientific methods, and these had been developed; the results had become more and more important. During the last half of the nineteenth century sanitary science and preventative medicine had done more to improve the physical well being of the race than they did in all the previous centuries. An abiding faith in the great value and truth of the discoveries of modern medicine and a confident assurance that future investigations would advance still further our knowledge justified the most sanguine hopes for the future great and rapid progress in sanitation.

Centennial Addresses.—Hon. Grover Cleveland, for the purpose of argument, divided humanity in two sections, one composed of a few doctors, and the other embracing the many millions of their actual or prospective patients. He appealed for himself and those millions. He believed he did not mistake the temper of his clients that he represented that there was growing up among them a feeling that there ought to be less mystery and high and mighty aloofness on the part of their medical advisers. They had long been wont to treat with a kind of amused toleration the names in pigeon Latin or Greek given by the doctors to very common things, and to diseases which already had names both simple and significant. But all this seemed to have much increased with the discovery of new remedies, and the chase after new diseases; and this increase had apparently been accompanied by additional mystery and additional inclination on the part of our doctors to remind them of their stately superiority. He desired to concede, without the least reservation, that they owed to the medical profession a debt of gratitude which they never could repay. But at the same time they were inclined to insist that in all that increased the usefulness and nobility of their profession this could not have happened without some corresponding advance in the intelligent thought and ready information of their patients along the same lines. He said they celebrated the close of the first century in the life and usefulness and honorable achievement of the Medical Society of the State of New York. If it had experienced vicissitudes, they were as nothing when compared with its many triumphs. And yet he believed there was no single incident of its career which furnished greater cause for satisfaction and joy than the harmonious unification of medical organization within the Empire State, which had just been accomplished under the name of this Society.

Dr. W. H. Welsh of Baltimore spoke of the deeds of men in the past, touching upon a few of the conditions which influenced the development of medicine in this country. Those influences were manifold and widely diverse and related to material political as well as social. He spoke of colonial medicine, of the inoculation against smallpox in 1721, and emphasized the fact that before the end of the eighteenth century substantial contributions had been made in this country to the knowledge, the prevention, and the treatment of the three great epidemics which afflicted the colonies, viz., smallpox, diphtheria, and yellow fever. In 1797 Smith, the father of medical journalism, published the first medical periodical. During the third decade of the nineteenth century a valuable impulse to medical education was received from influences which came from Edinborough and London. He referred to the activities of such men as Rush, Dake, Dudley, McDowell, Mott, Thatcher, Williams, Gross, and many others as well as the men from the frontiers along the banks of the Ohio. He said there was no reason to be ashamed of American medicine during the past century. We had led the way in the removal of abdominal tumors, the ligature of large arteries, in the treatment of deformities, in the study of appendicitis, and above all we first demonstrated the use of anesthesia in major operations, and had made also many and great advances in the practice of medicine and sanitation. We had also introduced the best methods of hospital organization and had the best medical library in the world.

Wednesday, January 31—Second Day

Election of Officers.—The following officers were elected: *President*, Dr. Joseph D. Bryant of New York (re-elected); *First Vice-President*, H. R. Ainsworth of Addison; *Second Vice-President*, F. C. Curtis of Albany; *Third Vice-President*, Allen A. Jones of Buffalo; *Secretary*, Wisner R. Townsend of New York; *Treasurer*, Dr. Alexander Lambert of New York. The following committees were appointed: *Arrangements*, chairman, W. J. Nellis of Albany, Arthur G. Root of Albany, Henry L. K. Shaw of Albany, Herman C. Gordinier of Troy, William C. Krauss of Buffalo, Edgar Vander Veer of Albany, Wendell C. Phillips of New York; *Hygiene*, chairman, John L. Heffernan of Syracuse, Wey and Hopkins; *Legislation*, chairman, Arthur G. Root of Albany, Ernest Wende, Egbert Le Fevre; *Scientific work*, chairman, Leo H. Newman of Albany, A. H. Bristoe, H. D Williams.

Members of the house of delegates, Willis G. MacDonald of Albany to succeed Dr. Lambert of New York, Edward E. Foster of New York to succeed Dr. Townsend of New York. The following *presidents of district branches* were appointed: First V. B. Gebuty, New York; second, H. B. Delatour, Brooklyn; third, F. J. Wheeler, Chatham; fourth, C. C. Madill, Ogdensburg; fifth, Nathan Jacobson, Syracuse; sixth, R. J. Loop, Elmira; seventh, J. F. Whitbeck, Rochester; eighth, De Lancey Rochester, Buffalo. The following *delegates* were appointed to the annual meeting of the American Medical Association: For two years, E. D. Ferguson, Troy, J. W. Grosvenor, Buffalo, E. Eliot Harris, A. Jacobi, Wisner R. Townsend, New York, Albert Vander Veer, Albany; alternates for two years, F. D. Reese of Cortland, Charles G. Stockton, Buffalo, W. G. Le Boutillier, F. B. Kinnicutt, J. A. Fordyce, New York, G. S. Comstock, Saratoga; delegates for one year, F. C. Crandall, New York, W. S. Ely, Rochester, H. L. Elsner, Syracuse, George Ryerson Fowler, Brooklyn, Roswell Parke, Buffalo, H. D. Wey, Elmira. Alternates for one year, C. S. Payne, Liberty, J. C. Davis, Rochester, C. P. Briggs, Ithaca, L. C. Ager, Brooklyn, L. J. Burrows, Buffalo, J. Orley Stranahan, Rome.

Report of a Case.—Dr. John F. W. Whitbeck of Rochester reported a case of simultaneous extrauterine and intrauterine gestation.

A Point in the Technique of Breast Amputation for Cancer.—Dr. Robert F. Weir of New York read this paper. He said that Halsted in addition to the radical operation which bore his name and was generally practised by surgeons went still further and showed that in some instances the rule that when the supraclavicular glands became enlarged the disease was beyond surgical relief, was a too stringent one. By him and others these glands had been attacked either, by an incision opening the posterior triangle of the neck or by the more severe and unnecessary procedure of sawing through the clavicle and thus exposing the supraclavicular space from an incision enlarging the breast wound upwards. The encouragement he had given to further effort in this direction only bore out the general rule that now firmly existed in all operations for cancer. This was, that all glands and lymph channels leading from the malignant focus should be examined and treated surgically if felt or seen to be involved. To carry out this rule in breast amputations it was necessary to open up and examine the supraclavicular region in each case where glands were found cancerously enlarged in the axilla. This was a proper precaution, but to avoid this additional incision he had been led to a little procedure which was the gist of his preliminary remark. Some eight or ten years ago, and certainly before the muscle removing or radical operations came into vogue, he found that in chasing up the enlarged lymphatic glands to the very point where the axillary vessels passed under the clavicle he could often carry his finger under the clavicle to one side of the vessels by pulling the arm vertically upwards and thus reached the gland, etc, well under and slightly above the clavicle, had become a fixed rule with him and he had employed it somewhat amplified in every breast amputation that he undertook. The skin of the neck, wherein no enlarged glands could be felt through the little or fore finger, could be carried in this way under or beyond the clavicle its full depth into the neck and the supraclavicular space behind the sternomastoid muscle fully explored. If enlarged glands were found in the region of the customary incision was made along the edge of the clavicle to the root of the sternomastoid muscle and up a short distance along its posterior border and the space cleaned out of glands and fat tissue If nothing was found the breast wound was closed as was usual save that he preferred to place a small cigarette drain in the hole bored alongside the vessels to be withdrawn at the end of twenty-four or forty-eight hours. This method of exploration had been tested so many times by him that he commended it to his surgical colleagues. As an additional reason for the extended use of this digital exploration, it need only be recalled that in nearly one-half the cases (47 per cent.) enlarged glands had been found where they could not be recognized by examination before the axilla was opened. A similar outcome had been met with in the neck in many instances, though, of course, not to as frequent a degree as in the axilla.

Dr. A. Jacobi of New York emphasized the value of methylene blue in cases of inoperable cancers, particularly abdominal.

Notes on Factors which Further Convalescence Following Abdominal Section.—Dr. Frederick Holme Wiggin of New York read this paper and called attention to the necessity of having patients under observation for a longer or shorter period prior to the operation when the circumstances of the case permitted it, in order that the digestive organs might be gotten into good condition, and that any tendency to insomnia might be overcome. The daily use of ergot in tonic doses, as well as massage, was advocated for this purpose. The advantage of selecting an early morning hour for the performance of the operation was pointed out as well as the necessity of careful preparation for the operation and a short period of anesthesia. The writer also advocated the washing out of the patient's stomach at the close of the operation and placing therein several ounces of a saturated solution of magnesium, or the hypodermic injection of eserine sulphate for the purpose of having gas and fecal matter pass the bowel within a few hours of the completion of the operation. The use of veronal in solution injected into the bowel to induce sleep during the first fifteen hours was also advised. The use of alcoholic and other stimulants was considered unnecessary and unadvisable, serving in his experience to lengthen rather than to shorten convalescence.

Some Comments on the Results of the Sanatorium Treatment of Pulmonary Tuberculosis.—Dr. John H. Pryor of Saranac Lake read this paper. He said that the annual report of the New York State Hospital for Incipient Pulmonary Tuberculosis recently transmitted to the Legislature afforded the first opportunity to review a complete year's work along a new line of progress. Careful scrutiny of the clinical statistics revealed some striking facts of great interest to the medical profession of this State. There was abundant evidence that this institution, created to establish and develop a new method of rational relief for the consumptive, had fulfilled its purpose with signal success. The results obtained were unparalleled and the object lesson would still be of inestimable value from an educational and benevolent standpoint. It seemed eminently fair and proper at this time to claim for the institution the pre-eminence which it deserved among the sanitoria for consumptives and to call attention to the wisdom of the novel system of administration and control embodied in law. This achievement was remarkable when it was realized that such a project could be made successful in New York State under present unfavorable conditions. The annual report contained a comparative table of results for the year ending December 31, 1905: The number of patients treated during the year, 293; the number of patients in hospital, December 31, 1905, 103; the number to be reported upon, 190. Of these 190 patients 25 remained less than two months in hospital and were not included in the comparative table of results. These 25 cases were reported upon in detail in the appended table concluding the report. In the majority of instances, patients who were discharged from the hospital after a stay of less than two months were favorable cases and improving at the time of discharge.

The classification of cases was made in accordance with the definitions adopted by the National Association for the Study of Tuberculosis. It was observed that 53 per cent. of the patients admitted were designated as incipient cases. This percentage showed an increase and was the highest attained as shown by collected reports and statistics. But

the increase continued and the remarkable statement appeared that on December 31, 1905, 70 per cent. of the inmates could be properly included in the group of early or incipient cases. The chief reasons for the improvement in the character of cases were probably to be found in the early cooperation and more careful work of the examiners in different cities and the recognition by the profession and the public of the vital importance of an early diagnosis and prompt treatment. It was safe to assume that 50,000 people in this State were suffering from pulmonary tuberculosis, and there must be thousands of the afflicted still in a curable stage. Some of the reasons why the disease was not detected early had been discussed in the MEDICAL RECORD, November 25, 1905. ("Some Facts Concerning the Early Diagnosis of Pulmonary Tuberculosis.")

It was most gratifying to learn that the appropriation for maintenance and equipment would probably be increased this year. The organic law explicitly stated that the institution should accommodate not less than 200 inmates. Although the trustees urged a sufficient appropriation to fulfill this requirement last year, economical officials succeeded in limiting the maintenance fund and the population to 100. The present buildings of the New York State Hospital should be filled with patients without any meddling with the law or any change in the methods of management. The transcendent importance, from any standpoint of early detection and prompt relief, was made strikingly apparent by the difference in the results obtained under similar conditions at the New York State Hospital. Of the incipient cases, 72 per cent. apparently recovered; in 24 per cent. the disease was arrested; 3 per cent. improved; and only 1 patient failed to improve. When compared with the results of treatment of the moderately advanced, which in the past had been frequently regarded as early and favorable, the picture was radically different and not as radiant as sometimes painted. Of this class 14 per cent. apparently recovered; the disease was arrested in 61 per cent.; 17 per cent. improved; 8 per cent. were unimproved. Of the advanced cases which were still regarded by physicians as incipient none apparently recovered. Disease arrested, 23 per cent.; improved, 62 per cent.; unimproved, 15 per cent. Thus the percentage of apparent recoveries in the incipient stage was more than five times greater than those in the moderately advanced stage, and seventy-two times greater than those in an advanced stage. The report showed 44 per cent. of apparent recoveries in all cases and 73 per cent. of apparent recoveries in the incipient stage In view of this revelation he asked if it was not timely to emphasize the fact that a new era had been inaugurated in the intelligent cure of the consumptive. Much had been written to show that tuberculosis in an advanced type was occasionally curable, and this contention was not disputed, but the suffering and hardship and the deprivation of home surroundings had been immeasurably greater than any lasting benefit obtained. No patient should be recorded as recovered until two or three years after health had been restored, and ultimate results should be accepted with reserve until five years had passed. The term arrest in relation to tuberculosis was a loose one, and the generally accepted meaning left too large an opportunity for individual opinion. There could be no doubt that an arrest was more lasting and more apt to be followed by recovery if the case was incipient. The care of a large number of patients who betrayed the evidence of invasion or beginning disease revealed occasional fallacies quite generally accepted. Sanatorium treatment had become largely an iron-clad routine practice and consisted principally of the open-air life, rest, and forced feeding. The time devoted to almost absolute rest in the early stages might be too prolonged, and continuous stuffing during a period of repose without study of the individual case, and the relation of dietetics might prove most irrational. Tuberculosis might or might not be arrested in its course while the individual was converted into an immobile aggregation of fatty cells. With active exercise or work the surplus melted away. Many so-called recoveries and arrests were apparent only so long as the individual confined any activity to involuntary functions. At this time the observation of Moxon seemed pertinent, "It is quite as important to know what kind of a patient the disease has got as to know what sort of a disease the patient has got." In Germany, the term "able to work" had been invented to describe a condition which denoted the character of the arrest or the degree of improvement. It meant simply that a relatively short stay in a sanatorium or a hospital would enable the patient to resume work for a very indefinite time, dependent largely upon the stage of the disease and the character of the occupation. It was difficult enough to maintain recovery under favorable conditions, and the greatest problem confronting those interested in sanatoria for the poor was to be found in the appealing necessity for suitable employment and surroundings for the patient who must resume the struggle for existence. The monotony of the form of treatment as practiced to-day should be relieved of some hardship by more amusement, and recreation provided. The net cost of maintenance paid by the State for the past year was $20,777.47. The cities and counties paid the balance. It would be interesting to know if the State has realized more fully on any other small investment. Finally, the expectation of permanent results hinged so largely upon the sanatorium treatment of the poor incipient case that attention was briefly invited to an anomalous condition becoming more noticeable each day. The poor person who received sanatorium treatment frequently enjoyed a much better chance for his life than the well-to-do patient who was unable to obtain proper supervision, discipline, frequent advice, and close attention to details. The New York State Hospital for Incipient Tuberculosis had won the right to expect the cordial support of the medical profession of this State. The experimental stage had been passed, and when the authorities at Albany were made to appreciate its just demands, the full benefits for which it was created would certainly be attained. New York city had led the way in prevention and New York State now led in method of management and results.

Dr. BEMIS of Jamestown, Dr. WALSH of New York, Dr. BERNSTEIN of Rome discussed this paper.

Toxic Arthritis.—Dr. HENRY A. FAIRBAIRN of Brooklyn presented this paper which was read by Dr. Bristow. He said that the term "rheumatism" was a misnomer and did not properly belong to a scientific nomenclature. It was the cause of much confusion and served as a cover for error. It was applied to conditions which could not be defined except by the process of exclusion. Their essential characteristic was yet to be revealed. Two characteristics were always present, viz., a toxemia accompanied by an inflammation of a part of the motor apparatus. It was possible to express these by the generic term toxic, and by appending the termination "itis" to the name of the part affected. This would exclude the other inflammations, the underlying cause of which was known, possible of definition and denomination. There seemed to be objections on the part of some to use the term infectious, as it carried with it the implication of communicability. The use of the term toxic would overrule such an objection, and at the same time describe the nature of the condition.

Dr. TOWNSEND of New York, Dr. VANDER VEER of Albany, Dr. KINNEAR of Clifton Springs, Dr. A. JACOBI of New York, and Dr. WALSH of New York discussed the paper.

Technique of Vaginal Section in Pelvic Diseases of Women.—Dr. J. RIDDLE GOFFE described at length the technique employed by him in doing vaginal section, illustrating his remarks with several diagrams.

Dr. MILLER of Syracuse, Dr. WIGGIN of New York, Dr. FORD of Utica, Dr. GALLANT of New York, Dr. BUDD of New York, and Dr. BROTHERS of New York discussed this paper.

Induction of Hyperleucocytosis in Infections.—Dr. W. G. Macdonald of Albany read this paper.

Oration on Surgery.—Dr. Roswell Park of Buffalo presented this oration, which was read by Dr. Henry R. Hopkins of Buffalo. He said that in no department of science had intellectual development brought greater changes in a comparatively brief space of time than in medicine. In the marvelous surgical accomplishments of the past thirty years one could see the tremendous effect of the development of a theory, since not until the germ theory of disease had been tested thoroughly and proven reliable could rational methods be adopted for combating the minute and deadly enemies by which mankind was always surrounded. Again the theory of evolution meant the establishment of an organic continuity between the lowest and the highest forms of life and taken in conjunction with an accurate knowledge of embryology it had much to do with explaining the congenital defects and arrest of development with which surgeons had to deal. He then referred to the greatest discoveries of the past century, especially anesthesia and antisepsis. The evolution of the surgical laboratory constituted the most conspicuous advance of surgery, and he divided the work done here into the minute and the gross. Under the minute work he included that which was purely histological, that which could be ranked as bacteriological, and that which could be spoken of as biochemical. Illustrative examples were given of the gross work in the surgical laboratory. He spoke of the work done in the surgery of the spinal cord, in cerebral localization, and particularly of the work that had been done with special organs. The development of the Medical Museum had done much to extend the capabilities of surgery. What was said of the museum could also be said of libraries. A considerable part of advance during the last twenty-five years had been due to improvement in general nursing which had been effected through the influence of these schools for nursing, and in the United States to-day he said there were as many as 20,000 graduate nurses. The skillful trained nurse was the surgeon's best adjuvant. One of the most important surgical developments of recent times was the more rational treatment of cancer. To New York State belonged the credit of being the first government in the world to inaugurate an institution for the scientific study of cancer, and the State Laboratory for the Investigation of Cancer, in connection with the University of Buffalo, was entitled the credit of being the pioneer institution of the kind in the world. The development of so-called military surgery had been another conspicuous feature of their growth. Another conspicuous feature was the development of the perfected modern hospital.

Dr. W. W. Keen of Philadelphia, who had been invited to discuss the oration, regretted that he had been late and heard but a portion of it. He briefly referred to the work that had been done by such men as Crile and Cushing on blood pressure, of Meltzer on the anesthetic properties of sulphate of magnesium, of Rogers and Beebe in the serum for the treatment of exophthalmic goitre, and he ended by stating that such work as was being done to-day by the younger men would further the interests of humanity and bring comfort and health to the sick and suffering.

(To be continued.)

Last Illness of the Great Conde.—A reader at the Bibliothèque Nationale has dug up the prescriptions for medicines which were ordered to Prince Condé in his last illness. A consultation of three physicians prescribed "a syrup made of rice, marshmallow roots, and sugar candies," and a blister to be applied night and morning. The distinguished patient failed to improve and a fourth doctor was called in, who ordered "two ounces of a preparation of hyacinths to fortify the heart and repair the exhausted forces," followed by "poppy water," "syrup of stag horns," "ipecacuanha," "liquorice," and "mistletoe roots." The prince lived through this treatment for six months, when he died, according to the death certificate, "of the malady from which he was suffering."

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundredth Regular Meeting, Held January 5, 1906.

The President, Dr. T. Mitchell Prudden, in the Chair.

A Case of Stokes-Adams' Syndrome.—Dr. Edward G. Janeway presented a woman, 51 years of age, who suffered from bradycardia, with Stokes-Adams' syndrome. He stated that at a meeting of the Society in the early part of 1900 he had shown a previous case of this same condition, together with tracings of the heart, jugular, and carotid pulsations, taken by Dr. Theodore C. Janeway in Professor Graham Lusk's laboratory. That was the case of Lieut. W., whose heart beats were at times as low as 20 per minute. In that case the pulsations of the jugular were readily recorded. In the present case the history showed that the patient had diphtheria in childhood, and fifteen years ago she had trouble in one elbow joint. Beyond these illnesses she had only suffered at times with colds. In November, 1904, while returning home from a hurried shopping trip, she had almost fainted on her way to the train. Five months later she had another attack after slight excitement. Since then, whenever she was hurried, she became faint, and recently she had an attack of complete unconsciousness, which came on after hurrying somewhat. She had no pain or discomfort of any kind, but was short of breath on exertion, and at times at night. Her legs had been somewhat swollen at times during the past summer, and her right knee had become stiff and painful in the course of the last three months. For the past year she had known that her puse was slow. From her account, its lowest rate per minute was 38; the highest, 44. Upon examination, the heart was found to be enlarged, the apex being beyond the nipple line when standing, and about the level of the nipple line when lying. There was a moderate lifting impulse. The heart rate ranged from 46 to 48 per minute. A systolic murmur was heard at the apex, and louder and harsher in the axilla and posteriorly, and at times a seeming extra systole was interposed. At the base, a systolic murmur, loudest along the left border of the sternum, between the second and fourth ribs, was audible. At the base, also, an occasional interposed beat could be heard. There was no sound which could be attributed to auricular action. Over the upper precordial area there was some lifting action. The arteries did not appear to be thickened. The veins in the neck beat faster than the arteries. The arterial pressure was 150 mm. mercury maximum; 95 mm. minimum. There was nothing found in the abdomen. The urine showed no evidence of renal disease. There was slight anemia. Tracings of the heart and carotid pulsations were readily obtained, but it was impossible to get a separate external jugular tracing. A study of these showed only a line for the jugular, but in the tracing of the carotid pulsation a number of extra waves were apparent—in all probability due to the external jugular pulsation. By inspection, and by very gentle palpation, these could be counted, and numbered about 115 per minute. On the tracing the carotid and cardiac pulsations were 42 to the minute. It had been the intention to test the effect of atropine upon the tracings, but, owing to the fatigued condition of the patient, that was not possible. She took 1-150th of a grain of atropine at four o'clock, and two and a half hours later had a severe fainting spell; when she recovered from this she complained of general numbness, and, according to the account of her attendant, her face was red (not pale) during the attack.

Dr. Janeway said that in the 64th Volume of the *Deutsches Archiv für klinische Medizin*, page 316, Professor William His, Jr., in 1899, published a case under the title, "Ein Fall von Adams-Stokes'scher Krankheit mit ungleichzeitigem Schlagen der Verhofe und Herzkammern (Herzblock)," in which he recorded a case observed in 1893, and spoke of the experiments he had made on animals to establish heart block by interfering with the auriculo-ventricular bundle bearing his name. He also stated that

he had presented his curves and charts at the International Congress of Physiologists, at Berne, in 1896. Unfortunately, when the patient, whose history he gave, died, Dr. His was unable to obtain a post-mortem examination. Dr. His' relations to this condition, Dr. Janeway said, did not seem to be generally understood. It was owing to the article referred to above that the tracings in Lieut. W.'s case were taken in 1900; the tracings in his case showed more frequent venous than arterial or cardiac pulsations. He referred to another case, that of a woman, in whom the pulse at times dropped to 12 per minute, and in whom not only unconsciousness, but convulsions occurred. She died during one of these attacks, and at the autopsy, which was made by Dr. LeWald, Dr. Theodore C. Janeway noticed that there was a gross lesion in a position to interfere with the His bundle. Dr. Janeway also referred to the experiments of Professor Erlanger, of the Johns Hopkins Hospital, together with his study of two cases of Stokes-Adams' syndrome recorded in the *Journal of Experimental Medicine;* also to the record of a case published, together with the post-mortem findings, in the *American Journal of the Medical Sciences* for December, 1905, by Dr. Stengel, of the University of Pennsylvania. He described a gross lesion in a position to involve the His bundle.

Clean Air.—By Dr. T. Mitchell Prudden. (See page 165).

Dr. W. Gilman Thompson said he hoped that the valuable paper of Dr. Prudden would receive the wide circulation that the importance of the subject entitled it to. Personally, Dr. Thompson said, he had long been interested in this subject, particularly from the hospital standpoint, and in two institutions with which he was connected he had for the past few years been conducting a crusade against the practice of dry sweeping. In one of these hospitals some interesting experiments had recently been carried out at his suggestion by the pathological department to determine the average bacteria contest of the wards under different conditions, with the following average result: On dry plates in a quiet ward eight colonies were obtained on culture; after moist sweeping, twenty-six; and after dry sweeping, sixty-nine. In connection with the dust analyses in the Subway, the speaker said that such an examination would be incomplete if it were limited to the dust content merely, without taking into consideration the presence or absence of other deleterious substances, such as carbon dioxide, nitrogenous waste, and other factors like the clinical examination of the employees who lived in the Subway atmosphere. While he, of course, did not wish to be understood as being an advocate of the inhalation of dust-laden air, and while the air in the Subway was, no doubt, noxious, he questioned whether the inhalation of dusty air was invariably as harmful as many supposed it to be. In that case it would be natural to see a great prevalence of certain pulmonary affections, particularly bronchitis, among persons who constantly worked in a dust-laden atmosphere, such as street sweepers, ash-cart drivers, etc., but such was not observed. On the contrary, such affections were not more frequent among those classes than among other laborers. Possibly the effect of the dust was offset by the fact that these men spent many hours in the open air, but after all one had to concede that while we all inhaled a great deal of dust and dirt, it was not necessarily deleterious, for so much depends upon the *kind* of dust, and in the lungs we possessed an active mechanism for the purpose of getting rid of these foreign substances. Dr. Thompson said that in the hospital experiments he had referred to, no specific microorganisms were found aside from the streptococcus and staphylococcus, fungi and spores. In one instance where a case of pulmonary tuberculosis had originated in the ward no tubercle bacilli were found in the ward dust, nor were there any of the microorganisms of influenza or pneumonia. Even more important than the method of getting rid of the dust in the room was the question of ventilation, and he had recently conducted experiments to compare the general foulness of hospital air in connection with the dust foulness. The carbonic acid content of pure air should never exceed four parts per 10,000, but one hour after twenty visitors had been admitted to a ward of 26 patients the carbonic acid content had increased to 5.13 per 10,000, while ten minutes later, after the windows had been opened, it had fallen to 4.34 per 10,000. This showed how the air that was intended for patients was vitiated by visitors, for whom no allowance was usually made in figuring the air content of the ward, under the pernicious system of "closed" ventilation. In addition to containing dust, nitrogenous waste, carbonic acid, etc., the atmosphere probably possessed deleterious properties of which we as yet knew nothing definitely, and which could not be measured by present physical methods. In pure air there was a certain property which we now crudely called "vitality," and its presence or absence could not be demonstrated by the thermometer, hygrometer, or any other instrument of precision with which we were acquainted.

Dr. John Winters Brannan said that the Metropolitan Opera House had installed the vacuum cleaning system, and that it was to be placed in all of the hospitals now under construction in the Department of Bellevue and Allied Hospitals, as well as in the old Bellevue building. Aside from its superiority over the older methods of cleansing, it was much more economical, as it did away with about 25 per cent. of the help.

Dr. Hermann M. Biggs said the problem discussed in Dr. Prudden's paper was a very difficult one, and involved, first of all, the education of the public. The Board of Health had done a certain amount of work along the lines suggested, but the task was such a stupendous one that nothing seriously had been attempted. The officials of the Subway and the Elevated Railroad had been communicated with at intervals in regard to the matter, and they had promised to institute certain reforms, but they had been spasmodic in character. The only way in which the reforms could be carried out would be by the continuous supervision of the Health Board officials, which would require a great increase in the force of the sanitary police, and the present outlook for this was not very promising. The sanitary squad now numbered 36, and it was inadequate for even its present duties, which included the abatement of nuisances, the control of cases of contagious disease, protection of the vaccination corps, the milk and food inspectors, etc.

Dr. Robert F. Weir said that Dr. Prudden, in his paper, had referred to the presence of germs in the spittle. This fact, some years ago, attracted the attention of surgeons, and by some of them masks were worn while operating in order to obviate the danger of infecting the wound in this way. The practice had practically been abandoned for the reasons, first, that the amount of such infective germs must be very slight; and, second, because the resistive powers of the normal tissues were such that they were able to neutralize a considerable amount of infection. While in our aseptic methods it was best to err on the side of safety, there was such a thing as carrying the precautions too far.

Dr. Beverley Robinson said that for a long time he had advised the use of a simple gargle—preferably one containing some antiseptic, like formalin or boracic acid, as an aseptic precaution, especially in susceptible individuals after being in a crowded place. The unfortunate drawback connected with such asceptic gargles was that they usually had an acid reaction; and while acid was good to kill microbes, it was bad for exposed dentine. Hence acid mouth washes were prejudicial, and should not be habitually used. This statement was commended to zealous, though frequently ignorant, dentists, and, perhaps, to a few practitioners of medicine.

Dr. Prudden, in closing, said there were, of course, many factors besides floating dust that might contribute to the insalubrity of the air. These varied under different conditions. Which was the most important was a question not discussed in his paper. As regarded the more common problems of ventilation, it seemed to him that too little

attention had been paid to the results of an experimental study recently made by Flügge, from which it appeared that the lassitude, headache, somnolence, etc., frequently experienced in crowded and ill-ventilated rooms were due not so much to poisonous products of human waste in the air as to a high temperature and an excess of moisture in the atmosphere.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 27, 1906.

	Cases	Deaths
Measles	1468	34
Diphtheria and Croup	348	41
Scarlet Fever	226	16
Smallpox		
Chickenpox	215	
Tuberculosis	404	178
Typhoid Fever	29	5
Cerebrospinal Meningitis	23	16
Typhus Fever		
Yellow Fever		
Cholera		
Totals	2,713	290

Congenital Tuberculosis.—Ralph Waldo Lobenstine says that not a single indisputable case of direct bacterial infection from the father is on record. Experiments have proven beyond a doubt, however, that the semen may contain tubercle bacilli in advanced general tuberculosis or severe tuberculosis of the testes. The infection is always transmitted through the placenta or decidua basalis from the maternal blood. The placenta shows in all cases tuberculous changes, but the degree of infection of the child does not, of necessity, depend upon the degree of those changes. The ovary may be the seat of the tuberculosis, but it has not been demonstrated that direct infection takes place through an infected ovum. The writer reports the case of a tuberculous mother who died on the sixth day after labor. The child died on the nineteenth day. The pathological diagnosis in the case of the latter was acute miliary tuberculosis of the lungs, liver, spleen, kidneys, and mesentery. Bronchopneumonia was present, also fatty liver and hyperplasia of lymphnodes. The writer sums up the pathology in the mother's case as follows: It may be assumed that the basal decidua was first affected, the tubercle bacilli traveling from the decidual sinuses to the covering of the villi, localizing there and causing thrombi in the adjacent intervillous spaces, destruction of the covering epithelium, entering the villous stroma, and finally reaching the chorion. The fetus was doubtless infected comparatively late, as suggested by the early stage of the tubercles in the child nineteen days old. Such children should not be allowed to nurse the mothers, but should be fed either on the milk of a wet-nurse or on modified cow's milk. They should not be allowed with the mothers nor in the room with other tuberculous persons. They should be kept in as pure an atmosphere as possible, and especial care should be given to the maintenance of the body temperature close to the normal.—*Bulletin of the Lying-in Hospital of the City of New York.*

The Practical Application of the Pressure Narcosis Method.—Brauer describes an apparatus designed to render possible operations involving opening the thorax. It differs from Sauerbruch's operating chamber in that Brauer raises the pressure of the air the patient inhales, whereas Sauerbruch rarefies the air in the chamber containing the surgeon and the patient's body up to the neck. Brauer warns against the use of any plan which involves intubation, and believes that he has solved the problem in the simplest manner possible by enclosing the patient's head alone in a glass-topped pressure box. This box is connected with a suitable air pump for maintaining the pressure, and has an expiratory valve which can readily be adjusted to any degree of pressure. The patient's head is enclosed in a cowl of soft rubber, leaving the features exposed, and armholes for the hands of the anesthetist are also provided with gauntlets of rubber so as to make air-tight contacts when the pressure is raised. The anesthetic may be given in the ordinary way, or preferably, by the Roth Dräger oxygen-chloroform apparatus. The apparatus is designed to permit of the greatest possible ease of manipulation and control of the patient's condition, and an important feature toward this end is believed to be the fact that the anesthetist and operator are not separated by a partition as is the case in the methods of Sauerbruch and Engelken. The pressure necessary is lower than is generally believed, and a tension equal to 6–8 cm. of water, 10 cm. at the most, is amply sufficient. The author thinks that the apparatus will be useful not only in thoracic surgery, but also for applying pneumatotherapy.—*Deutsche Medizinische Wochenschrift.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended January 27, 1906.

A NEW METHOD OF TESTING THE FUNCTIONS OF THE DIGESTIVE APPARATUS.

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

About two years ago[1] I described a method of estimating the motor functions of the digestive apparatus. It consists in having the patient swallow a number of small porcelain or glass beads, which are later looked for in the feces by means of my stool sieve.[2] The time elapsed between taking them and the reappearance of the first beads indicates the length of their sojourn in the digestive apparatus. I tried at that time to coat these beads with substances which are digested in the stomach or bowels, in order to be able to judge the functions of the various parts of the digestive apparatus. This idea, however, was not feasible, on account of the difficulty of preparing the test beads.

At the beginning of this year I conceived the plan of attaching solid food stuffs to glass or porcelain beads (by drawing them through the opening in the bead and tying them on with a silk thread) and then to have them pass through the stomach and bowel in order to see finally what remained attached to the bead. It is self-evident that a substance which is entirely digestible will disappear, whereas indigestible substances will be found in the feces attached to the bead.

Indeed it is possible in this way to ascertain the digestibility of many food substances in normal as well as pathological conditions.

Physiological.—I tried at first to find out how various food stuffs behaved in the stomach and bowel of apparently healthy persons. For testing the work of the entire digesive tract it was only necessary to have the beads with the food attachments traverse it and then examine them.

To test the work of the stomach only, the beads with the food substances attached are tied to a long silk thread, placed in a gelatin capsule, the thread being drawn through the capsule, and then swallowed. The thread was passed into the stomach only for a distance of 50 to 60 cm. from the lips, and then the food stuffs were exposed for from four to six hours to the action of the gastric juice. At the end of this time the beads were again drawn up by the silk thread and carefully examined. In this way the extent of the gastric digestion could easily be estimated. Both methods combined (stomach thread test and plain bead test) enabled us to judge of the digestion in the stomach as well as in the bowel.

The following experiments have been made on healthy persons:

1. *Catgut and Meat.*—September 26, 1905. Cr. and Dr. K. each swallow a capsule containing three catgut (white) and three corned beef (red) beads. Eighteen hours' later two white and two red beads without cagut or meat are found in Cr.'s movement. Thirty-six hours after taking capsule K. has a movement in which five beads (three white and two red) without catgut or meat are found.

2. *Catgut and Tendon (Raw).*—October 12, 1905. Dr. H. E. swallows a capsule with three catgut (white) and two tendon beads (yellow). After seventeen hours all five beads appear in the stool. The white beads are free, but the yellow ones still hold the tendon.

3. *Raw Chicken Skin and Raw Beef.*—October 15, 1905. Dr. H. E. swallows two yellow beads with raw chicken skin attached and three red ones with raw beef. One of the latter has the silk thread attached arranged in such a manner that it can be drawn up again. Six hours later the red bead is drawn up from the stomach. The beef is still attached. Twenty-four hours later the bowels move. Two yellow and one red bead were found all without food particles.

4. *Raw Potato and Apple.*—October 23, 1905. Dr. H. E. takes a capsule containing two beads (blue) with raw potato and its skin attached and two white ones with raw apple and peel. Twenty hours later a blue and a white each are found in the stool. To the blue bead remains attached a piece of potato skin (no potato substance); to the white bead a piece of apple peel without any apple. In the potato skin starch could not be demonstrated microscopically by means of iodine; only a little erythrodextrin was still present.

October 29, 1905. Cr. takes a capsule with two blue beads containing raw potato with the skin. Seventeen hours later both beads appear in the stool. There are still particles of potato present, starch reaction is strongly positive.

October 27, 1905. Dr. H. E. swallows some beads attached to a silk thread and placed within a capsule, containing catgut (white) raw chicken skin (yellow) and raw potato with skin (blue). Since the thread is made about fifty centimeters in length the beads cannot enter the intestinal tract. Seven hours later the thread with the beads is drawn up from the stomach. Catgut has disappeared; the other substances are all present. Microscopically the potato shows a strong iodine reaction and plenty of starch granules.

5. *Raw Potato and Fish Bones.*—October 29, 1905. Dr. H. E. takes a capsule with a blue (raw potato with the skin) and two green beads (fish bones). After about twenty hours the blue bead is found in the stool with potato attached. The skin as well as the potato substance itself are well preserved; starch reaction positive. After forty-four hours the green bead without fish bones is found in the stool.

6. *Wax and Paraffin.*—October 31, 1905. Cr. and Dr. H. E. take each a capsule with three green (wax) and three blue (paraffin) beads. After twenty-four hours in Cr. and thirty-six hours in Dr. H. E. all beads are found in the stool. Both wax and paraffin have remained on the beads.

November 1, 1905. Dr. H. E. swallows a fish bone bead and a paraffin bead attached to a silk thread. Three and a-half hours later the silk thread is drawn up. The fish bone has disappeared and the paraffin has remained unchanged.

7. *Stearic Acid.*—November 2, 1905. Dr. S. takes a capsule with two brown (stearic acid) and one blue (fish bone) beads. November 4, 1905, the three beads are found in the stool. The brown ones contain the stearic acid, the blue one is empty, the fish bone having disappeared.

8. *Suet and Mutton Fat.*—Dr. S. takes a capsule with two yellow (suet) and two white (mutton fat) beads. Thirty-six hours later the four beads reappear in the stool. The yellow ones are empty; the white ones show a small thin layer of yellowish substance within their lumen.

November 26, 1905. Cr. takes a capsule with three beads; a large one, containing a fish bone, a medium-sized one, containing mutton fat, and another one with mutton fat enclosed in gauze. Four and a-half hours later the bead surrounded with gauze is found in the stool. It does not contain any fat. Seventeen hours later another stool produces a fish-bone bead with the fish bone intact.

9. *Boiled Potato with Skin.*—November 11, 1905. Mrs. E. takes a capsule with a yellow (potato boiled for two minutes) and a pink (potato boiled for four minutes) bead. November 14, 1905, a pink and a yellow bead are found in the stool with potato skin attached, but no potato substance.

10. *Boiled Potato and Mutton Fat.*—December 14, 1905, Dr. S. takes a capsule with two yellow potato beads (one in gauze) and two mutton-fat beads (one in gauze). Eight hours later two beads are found in the stool, a yellow one without potato but with the skin, and a white one with still a little mutton fat left in the lumen of the bead. Twenty-four hours later the yellow bead with gauze containing only potato peel is found. Microscopically no starch. Forty-two hours later the mutton-fat gauze bead is found completely empty.

Remarks.—These experiments in healthy people show that both catgut and fish bones are digested in the stomach, whereas boiled or raw meat (beef), raw chicken skin, and raw as well as boiled potatoes do not disappear altogether in this organ. The muscles show a swelling and loosening of the fibres. Raw muscle fibre and chicken skin disappear in the intestines; tendons, however, remain undigested. Raw potatoes show a varying condition, sometimes disappearing entirely, sometimes going through unchanged; boiled potato usually seems to be digested in the bowel, whereas the skin of potato (either raw or boiled) always reappears unchanged.

Fats with a very high melting point, as lard, stearic acid, wax, paraffine, are not absorbed in the intestine; suet and mutton fat are digested in the bowel.

Experiments made with mutton fat show that it remains unchanged in the stomach. We also tried to determine whether the disappearance of the mutton fat in the intesines was a purely chemical process or a mechanical one, produced by the epithelium of the intestine. For this purpose we experimented with mutton fat surrounded by gauze. It is evident that mechanical processes are excluded in this manner, whereas the chemical action remains. All the mutton fat in the beads enclosed in the gauze disappeared. This proves that chemical processes play the principal part in the absorption of mutton fat, which has a melting point of 50 degrees Celsius. Thymus gland and potato were subjected to the same experiment. Here also it was shown that digestion was not interfered with by the gauze envelope.

Pathological.—The behavior of the substances just enumerated in normal digestion being known, they can be employed for testing the digestion in disease.

A. *Testing the Gastric Functions.*—I. *Catgut.* First a few tests were made with catgut beads. It has been known for some time through the investigations of Ogata[3] and that indefatigable worker, Ad. Schmidt,[4] that connective tissue is not digested in the intestines, but in the stomach. Therefore, connective tissue fibres are found unchanged in the stool when the stomach functions are disturbed (achylia gastrica). Catgut consists principally of connective tissue and ought to behave like the latter. This fact induced Sahli[5] to employ the catgut in a new stomach test called the "desmoid test." He enclosed methylen blue in a rubber bag and tied it securely with catgut and then had the patient swallow it. As soon as the catgut has dissolved in the stomach the bag opens, methylen blue is absorbed and appears in the urine, giving it a blue color. If no gastric juice is present the rubber bag remains closed and the urine is not discolored. I have used catgut in a similar manner to test the functions of the stomach. Catgut beads are swallowed in a gelatin capsule and the stool is subsequently examined by means of the stool sieve until the beads reappear either with or without the catgut.

The following tests were made with catgut beads:

1. W. H. W., with pronounced hyperchlorhydria, takes a gelatin capsule with four catgut beads. Twenty-four hours later three beads were found in the stool. Forty-four hours later one bead. Catgut had disappeared from all.

2. Mrs. Anna F., with achylia gastrica and chronic enteritis, takes a gelatin capsule with four catgut beads. Ten hours later two beads were found, twenty hours later two more. The catgut remained attached and unchanged in all of them.

3. Wm. G., suffering from chronic myocarditis, cirrhosis of the liver and achylia gastrica, takes a gelatin capsule with four catgut beads. Thirty hours later three beads with catgut attached are found in the stool.

4. Mrs. Amelia K., with achylia gastrica, takes four catgut beads in a gelatin capsule. Thirty hours later four beads are found without catgut.

From these experiments we can draw the conclusion that gastric juice must be absent if the catgut is found unchanged in the beads. If it has, however, disappeared from the beads we cannot positively assert that gastric juice is present because case four shows that under certain conditions (with intact intestinal digestion) catgut may be digested even if achylia gastrica is present.

2. *Fish Bones.*—Since catgut therefore cannot be utilized as a positive indicator of the presence of gastric juice I employed fishbones for the same purpose.

Faber[6] was the first to call attention to the fact that in patients with achylia gastrica fish bones reappear in the stool. I therefore made various experiments with fishbones. First I was able to experimentally prove that fish bones placed in gastric juice in a test tube and kept at body temperature dissolve easily. Fish bones were also digested in the stomach of healthy persons as shown above. The question now was, whether fishbones could be digested in the intestine or not.

To decide this question I tied fish bones into the lumen of the beads and surrounded them with

a heavy coating of mutton fat. This I gave to persons in whom previously the test with plain fish bone had been positive. As the mutton fat is not changed in the stomach the fish bone cannot be attacked in this organ. In the small intestine the fat disappears and the fish bone is exposed to the

Fig. 1.—1. Catgut bead; 2. thymus bead; 3. fish bone bead; 4. potato bead; 5. meat bead; 6. muttonfat bead; 7. digestive test capsule.

action of the pancreas and intestinal secretion. If it, therefore, reappears intact in the stool, it shows shat fish bones are not acted upon in the intestine. My experiments with fish bones and mutton fat coating which were several times executed, always gave the same result, viz., a reappearance of the fish bones in the stool.

We can, therefore, conclude from a positive result of the fish bone test that gastric juice must be present. We are not allowed to conclude from a negative result that gastric secretion must be absent. It is evident that the fish bone requires a certain amount of time for digestion, and that if it leaves the stomach before this time, the fish bone will proceed through the intestinal tract unchanged.

This will be evident from later tests, and it really occurs off and on.

B. *Testing the Intestinal Functions.*—All substances enumerated in part one which are little changed or not at all in the stomach and are entirely digested in the bowel may be utilized in testing the intestinal functions.

Adolph Schmidt's[7] method introduced in the last few years of testing the intestinal functions is based upon the microscopical examination of the

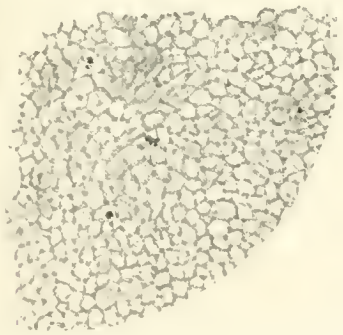

Fig. 2.—Potato skin (refound in the stool) under the microscope, after addition of Lugol's solution: very few starch granules and some erythrodextrin visible.

stool for muscular fibers or connective tissue, etc. after a test diet which has to be kept up for three days or longer. This diet consists of one and a-half liters of milk, two eggs, 100 gm. zwieback, 50 gm. butter, 125 gm. beef, 190 gm. potatoes and the gruel from 80 gm. of oatmeal daily. Normally after this diet there are no muscular fibers visible macroscopically, and microscopically only small fragments. An examination like this lasts several days and is rather tedious.

Instead of this we can just as well follow the changes of food substances that have been attached to beads and passed through the digestive tract. For albumen we can use raw meat, for starch potato (boiled two minutes), for fat digestion mutton fat. If the intestinal functions are good or normal, all these substances will disappear from the beads during their passage through the digestive tract; if there are, howver, disturbances, we can recognize them from the reappearance of food substances attached to the beads. In connection with the intestinal function the pancreatic function may be tested by a piece of raw thymus surrounded with gauze and with bead attached.

With intestinal and pancreatic function intact the thymus will entirely disappear; if the functions are not normal the thymus remains unchanged and the nuclei also. In disturbances of the stomach and intestinal functions, the pancreatic function being normal, a part of the gland will reappear, the nuclei, however, having entirely or nearly disappeared.

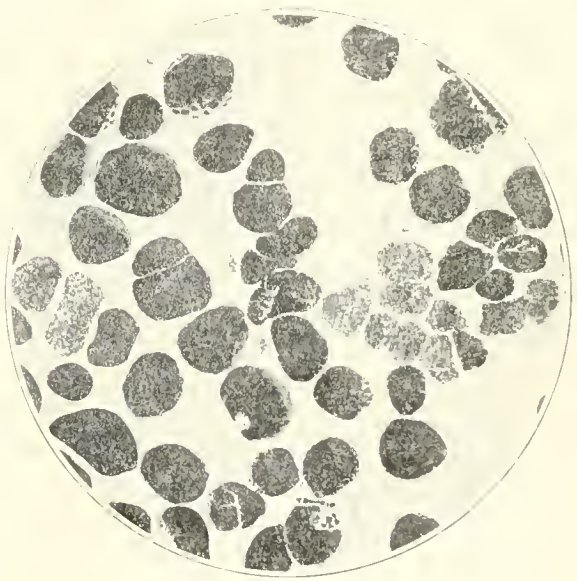

Fig. 3.—Potato substance (after passing of a potato bead through the digestive tract); microscopical view, after addition of Lugol's solution: many starch granules, almost unchanged; some are converted into erythrodextrin.

C. *Testing the Entire Process of Digestion (Stomach, Bowel, and Pancreas).*—In order to test the work of the entire digestive tract, it is best to give a gelatin capsule containing the following test substances attached to beads of different colors: (1) Catgut (white bead), (2) fish bone (large green bead), (3) raw beef (red bead), (4) potato with skin, boiled two minutes (yellow bead), (5) mutton fat (purple bead), (6) thymus gland surrounded by gauze (blue bead).

The different colors enable us to differentiate the various substances after they have passed through the digestive tract. Such a capsule with the six test substances might be called a "digestive test capsule."

I have added a drawing (Fig. 1) of one of these digestive test capsules as well as of each individual test bead in order to show the manner of attachment of the various food substances to the beads.

Method.—The patient is given a digestive test capsule shortly after a meal (best after breakfast

or dinner) and the subsequent stools are examined by means of my stool sieve, until all six beads have been recovered. These are then washed with a little cold water and then well inspected to see whether the substances are still attached or not. The gauze sack (surrounding the thymus) is cut open and examined for remnants of thymus. If any is present a microscopical examination after staining with methylen blue would be necessary in order to determine the presence or absence of nuclei. The time of the stool, the number and kind of beads found, must be noted.

The occurrence of the first beads marks the time taken to traverse the digestive tract and thus indicates the motor functions of the digestive apparatus.

Observations on This Method of Testing the Functions of the Digestive Apparatus.—I shall briefly summarize all the cases in which I have made the tests of the digestive function.

Case I.—October 25, 1905. Peter L., with achylia gastrica, takes a gelatin capsule containing two white (catgut) and two red (raw beef) beads. October 26, 1905. Four beads without catgut or meat are found in the stool. October 29. Patient takes two green (fish bone) beads and one blue (raw potato) bead. October 30, 8 A.M. Nineteen and a-half hours after taking the stool contains all three beads, fish bone and potato being attached. November 2. The same patient takes two white (catgut) beads and one blue (fish bone) bead and one brown stearic acid bead. November 3. White bead found without catgut. November 4. Blue bead with fish bone attached found.

Case II.—October 29, 1905. John P., suffering from dilatation of the stomach, absence of HCl, and cirrhosis of the liver, takes a capsule with two white (catgut) and one green (fish bone) bead. Forty hours later three beads in stool, containing both catgut and fish bone intact.

Case III.—November 11, 1905. Mr. B., with hyperchlorhydria and neurasthenia, takes a digestive test capsule. Forty hours later four beads, and 60 hours later two more are found. The potato bead contains only potato skin (Fig. 2) without any potato substance; the fish bone is attached to its bead; all other beads are empty. November 15. Stomach thread test. Mr. B. takes fish bone, catgut, and meat beads attached to a silk thread and enclosed in a capsule. Four and one-half hours later the thread is removed from the stomach, the meat is still present, catgut swollen but still attached, the fish bone is missing. November 13 Mr. B. swallows a thymus gland bead and a mutton fat bead attached to a silk thread and enclosed in a capsule. Six hours later the thread is removed. The mutton fat bead is unchanged, the thymus gland is also present, showing the nuclei well, microscopically.

Case IV.—November 24, 1905. J.C.R., with atony of stomach and hyperchlorhydria, takes a digestive test capsule. Thirty-six hours later three beads are found; fifty hours later the other three. They are all empty; of the potato only the skin remains. December 2. The same patient takes a bead with thymus surrounded by mutton fat, the whole enclosed with gauze and a bead with fish bone coated with mutton fat. December 3. Twenty-one and a-half hours later both beads are again found. Thymus is present in the gauze; nuclei being somewhat diminished; fish bone is also present; some fat in the lumen of both beads.

Case V.—November 15. Alfred S., with achylia gastrica and chronic enteritis, takes a digestive test capsule. November 17. Two beads are found, one pink one containing only potato skin, and a blue one containing thymus (not much changed). The potato skin shows no starch; only traces of erythrodextrin. The thymus gland contains only few nuclei, but the connective tissue is well preserved.

Case VI.—November 20, 1905. Samuel O., with chronic ulcer of the stomach, takes a digestive test capsule. Forty hours later five beads are found in the stool; catgut and meat are digested, fish bone present, thymus present, but few nuclei, potato substance present (Fig. 3); starch reaction positive.

Case VII.—November 20. Morris L., with typhoid fever, in the stage of defervescence, takes a digestive test capsule. Twenty-seven hours later five beads are found in the stool. Catgut and meat are digested; potato undigested, thymus undigested, nuclei nearly absent, fish bone still attached. The same patient with normal temperature and being convalescent, takes another test capsule on December 1. Fourteen hours later four beads are found in the stool. Thirty-eight hours later one bead, sixty-two hours later another. Everything has disappeared, only the fish bone is still present.

Case VIII.—December 1 1905. A. G. with severe ulcerated colitis and hemorrhages, takes a digestive test capsule. Twenty-six hours later four beads are found in the stool, fifty hours later two beads; everything has disappeared but the fish bone.

Case IX.—November 21, 1905. H. C., with cancer of the transverse colon, takes a digestive test capsule. Thirty-six hours later two beads are found, fifty hours later again two, also after ninety-four hours. All the beads were empty; only the potato skin is attached to the one, but no potato pulp.

Case X.—December 12, 1905. Dr. F., with alcoholic gastroenteritis, cirrhosis of the liver, and diabetes mellitus, takes a digestive test capsule. Thirteen hours later three beads are found in the stool, fish bone, catgut, and meat with all the substances intact. Nineteen hours later the mutton fat bead appears, the fat occupying the entire lumen of the bead. Twenty-three hours later the thymus gland bead makes its appearance also unchanged; nuclei are plainly visible and do not seem to be diminished. December 16, 1905. Dr. F. again takes a digestive test capsule. Six hours later three beads in the stool; thirteen hours later another bead, nineteen hours later another one. In all five beads were found; they all carried the test substance and the thymus was found in the gauze with nuclei unchanged.

Epicrisis.—From the cases just described we can see that this method gives us a deep insight into the functions of the digestive tract. It is, for instance, of interest to observe that in spite of cancer of the digestive apparatus, occasionally, the digestive functions are perfectly normal (Case 9). In such cases the seat of disease is circumscribed and the digestive apparatus is not much damaged.

The digestive functions were most disturbed in Dr. F. (Case 10), where all the tests were negative. He probably had a severe lesion of the pancreas and this supposition was corroborated by the presence of diabetes and the nondigestion of the nuclei of the thymus gland.

In achylia gastrica the catgut is sometimes digested, sometimes it is not, whereas the fish bonse were always undigested. Thymus gland also remained, although the nuclei were always more or less changed.

In hyperchlorhydria no impairment of the digestive functions was noticeable.

The number of cases examined is too small to permit of generalizations, still it shows that the method as such is serviceable and worthy of further investigation.

WHAT IS THE CLIMACTERIUM?

By SAMUEL WYLLIS BANDLER, M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF GYNECOLOGY, N. Y. POST-GRADUATE MEDICAL SCHOOL; FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS; ADJUNCT ATTENDING GYNECOLOGIST TO THE BETH ISRAEL HOSPITAL.

According to Fehling the evidences which accompany a normal menopause are congestions, flushes, and sweatings, which have a tendency to disappear after one-half to one year. They sometimes last for years. There may be superimposed palpitation, dizziness, nervous symptoms of the stomach and intestines, a feeling of flatulence and distention, neuralgias, especially costal, sleeplessness, an anxious feeling, mental unrest, and irritability. Depression and melancholia are seldom found. The symptoms are worse in women formerly neurasthenic or hysterical. The symptoms are worse if the senile uterine changes are marked and sudden. They are less if the senile uterine changes come on slowly. Physical disease is seldom noted.

It is important to mention the fact that menopause is generally considered an essential evidence of the climacterium. This is not so. One of the important complications of the climacterium are great uterine bleedings, regular or irregular in their occurrence. With these bleedings the essential constitutional and nervous symptoms of the climacterium may be present in full force. Because of the presence of the bleedings, the fact that the climacteric symptoms may be present is generally overlooked, so strong is the idea that only a cessation of the menstruation is proof of the onset of the climacterium

According to Martin, the symptoms, after castration, are rushes of blood to the head, combined with a feeling of anxiety. There is often added thereto palpitation, dizziness, tinnitus, and sweating. These symptoms occur in various combinations, often repeated several times a day. Continuation of these conditions leads to feelings of weakness, to headaches, sleeplessness, etc. The symptoms usually improve after two or three years, but sometimes continue for five or six years.

It is generally considered that after hysterectomy the annoying symptoms of the climacterium are absent if the ovaries be left behind. This view is an erroneous one. The ovaries gradually atrophy and their function disappears at various periods, generally at the end of the second or third year. Then the climacteric annoyances come on, as a rule in slighter degree than is the case when the ovaries are removed together with the uterus. The action of the ovaries in preparing the uterus for pregnancy is certainly their main purpse. When the uterus is removed and menstruation ceases, the ovaries, in the course of time (for what exact reason we cannot determine), disappear. In these patients, after the lapse of time, the usual climacteric symptoms appear, but in slighter degree. Here we have evidences of the results of ovarian insufficiency.

According to Baruch and others the annoyances after castration are most marked in nervous and hysterical women. They find it hard to distinguish between their "nervous symptoms" and those which are due to the menopause. That is the difficult question. Are the severe changes at the menopause due to absence of ovarin and the consequent metabolic changes in predisposed individuals only, or are they due entirely to the menopause or the climacterium itself without regard to predisposition? It can certainly be said that we often enough see severe climacteric annoyances in women who before this stage showed absolutely no characteristics which could be considered nervous. On the other hand we see quite often no bad results at all after castration in patients who before operation were certainly nervous, nervous even years before the condition for which they were operated upon existed. In fact we often see such patients very much improved after operation. These various factors speak for the specific causation of climacteric symptoms.

The symptoms caused at the climacterium, artificial or natural, are certainly due to diminution or absence of function on the part of the ovary, as is also proved by the good results obtained by treatment with ovarin.

Mainzer, in the clinic of Landau, found that disturbances in the vasomotor system, resulting after castration, disappear upon the administration of ovarin, that disturbances after the natural climacterium are benefited, that the results in primary or secondary amenorrhea are satisfactory, but that no effect is exerted upon general hysteria.

In the light of our present knowledge we know that, aside from furnishing the ovum, the ovary possesses an internal secretion. This internal secretion produces various normal manifestations in the pelvic region and in the body generally. We know that the ovary is essential to a proper preservation of the female genitalia, most particularly is it essential to a proper preparation of these structures for pregnancy. We believe likewise that the ovaries are related to pathological conditions associated with pregnancy, such as hydatid mole and chorioepithelioma. We know further that the ovaries stand in relation to those sclerotic and atrophic changes in the uterus which produce climacteric bleedings. Aside from this, preservation of the ovaries has a bearing on other physical and mental conditions of the patient as can be recognized by the changes which occur when the ovaries gradually atrophy at the menopause, or by the changes occurring when the ovaries are removed by operation.

That the ovarian secretion is not of essential importance is evidenced by the fact that a goodly proportion of women go through the menopause without noticeable annoyances, and that

in a fair proportion of the operative cases there is little or no annoyance at all. The same variations in degree, in intensity, and in the duration of symptoms as are observed in the natural climacterium are to be likewise observed after surgical castration. The disturbances after operation are at first mainly of a vasomotor nature and are accompanied by psychic unrest. Why do these disturbances occur? Is it because the ovarian secretion furnishes something which is actively necessary, or is it because the ovarian secretion nullifies some other substance produced in the body? During the natural climacterium the annoying symptoms are generally worse in those patients in whom atrophic changes in the uterus occur rapidly while they are less annoying if these changes go on slowly. The patients who have irregular and profuse bleedings often, but not always, suffer less from the annoying constitutional and nervous symptoms. It seems as if with the loss of blood there is expelled from the body a toxic substance which, when retained, produces the phenomena of which we are speaking. After the menopause the system gradually becomes accustomed to this condition of retention, or else the retained products are no longer produced and the annoying evidences gradually disappear. After surgical castration, even in the severe cases, the body becomes accustomed to the absence of the ovarian secretion, yet many cases have few or no symptoms at all, which fact shows that the same variations are observed in the menopause after castration as are noted in the menopause occurring along normal lines.

Glaevecke says "castration develops an artificial climacterium, which in all points resembles the natural, and the female enters through castration prematurely into the climacteric age. Castration cuts deeper into the general organism of the female than does total extirpation, and we must rate the mutilating effect of the first higher than the latter. Very noticeable are the changes in the mental sphere, where we generally see a depression of temperament, which often increases to marked melancholia and in these cases goes on to a real psychosis."

Pfister claims that "the so-called mutilation (of castration) should not be rated so high, in that the influence which the female ovary exerts on the female organism is much overrated."

Alterthum says the complete removal of the ovaries "does not at all produce the injurious results upon the mental and physical condition of the female as has generally been accepted."

Abel says that "after removal of the uterus, the ovaries enter into a more or less rapid atrophy which causes, already before the age limit of the natural climacterium, a complete disappearance of ovarian function. It is certain that after removal of the ovaries we see *at once* all the physiological accompaniments and anatomical consequences of the climacterium developing in a relatively short time, more immediately and sharper than they generally do at the natural age limit. Not so after the removal of the uterus. Here the transition is much more natural and milder."

Leaving out of consideration the varying and diametrically opposed views as to the value of preservation of the ovaries in operations which render pregnancy no longer possible, let us consider the symptoms which occur when the ovaries gradually atrophy or are suddenly removed.

The symptoms which occur in either of these instances are mainly the following: (1) Flushes with or without reddening of the skin, frequently followed by a sensation of cold and sweating; (2) palpitation of the heart, (3) dizziness, (4) headaches, (5) sleeplessness, (6) disturbances of digestion, (7) irritability of temper, (8) tendency to either mental depression or excitement, (9) various "nervous" manifestations, especially psychical unrest, (10) psychic disturbances. A comparison of all these symptoms with those which are known as "hysterical symptoms" or as "neurasthenic symptoms," and with the symptoms of aberrant Basedow's disease, shows a marked resemblance more than sufficient to prove the frequent possibility of error and the need of an exact differential diagnosis, in cases about the climacteric age especially.

In the study of the symptoms of the climacterium either natural or artificial, I have long been accustomed to consider these cases as instances of what I have termed "relative Basedow's disease," because the symptoms resembled to a considerable degree the symptoms of Basedow's disease. The more important reason was the fact that I considered the symptoms in climacteric cases to be due to hyperthyroidism. Since Basedow's disease was considered to be due to hypersecretion of the thyroid, the term "relative Basedow's disease" seemed an apt one.

For instance, Osler considered the typical symptoms of Basedow's disease to be tachycardia, exophthalmos, goitre, and tremor, "which is of great importance in the diagnoses of early cases." Among the other symptoms mentioned by Osler, are anemia, emaciation, slight fever, vomiting, diarrhœa, pruritus, irritability of temper, change in disposition, great mental depression, weakness of muscles, especially a "giving way" of the legs. According to Osler, thyroid extract given in excess produces symptoms not unlike those of Basedow's disease, viz.: tachycardia, tremor, headache, sweating, disturbances of menstruation, etc. The use of thyroid extract, he says, usually aggravates the symptoms of exophthalmic goitre. According to Gideon Welles, thyroid administered in large amounts produces the following symptoms: Palpitation of the heart, headache, nausea, vomiting (if the dose is excessive), excitability irritability, sleeplessness, diarrhœa often. Moebius says that "Basedow's disease is an affection of the body through morbid activity of the thyroid gland."

The following theories, among others, are mentioned by MacCallum as possible explanations of Basedow's disease:

(1) A general neurosis. Constant changes in the thyroid, however, cannot be explained on this basis.

(2) Moebius' theory of hyperthyroidization. However, not *all* symptoms can be caused by injecting thyroid extract into animals. Histologically we cannot say that the gland is secreting actively. Results of operation are not uniformly good. A combination of exophthalmic goitre with myxedema speaks against the exclusive rôle of the thyroid.

(3) Lesions of the sympathetic; this explains only haltingly a few of the symptoms.

(4) Parathyroid inactivity, or insufficiency. Disturbance of the thyroid secretion causes myxedema; disturbance of the parathyroid causes exophthalmic symptoms. This might explain combinations of these conditions. This latter theory seems to offer some promise.

On the other hand it is the opinion of Thomson that intestinal intoxication is the probable cause

of this disease. In his opinion the points which disprove that the thyroid is the cause are:

(1) Simple goitres cause no symptoms.

(2) Graves' disease often occurs without goitre.

(3) The severity of the toxemia in Graves' disease bears no relation to the degree of thyroid hyperthrophy.

(4) Even though myxedema and Graves' disease do form an absolute contrast, yet we have no other known example of specific disease due to hypersecretion on the part of any gland.

(5) The administration of thyroid causes giddiness, cardiac palpitation, and moderate and temporary tachycardia, but not the important and characteristic symptoms of Graves' disease.

(6) The frequency in women. He explains this "by the proneness of women to gastrointestinal derangement in connection with menstruation, pregnancy, and the menopause."

(7) Treatment based on the theory of gastrointestinal origin of the disease is so superior that it confirms the idea that diet and digestion, and disorders connected therewith, are the chief factors in the etiology.

"Whether, therefore, the constitutional symptoms of Graves' disease be due to excess of thyroid secretion or to atrophy of the parathyroids (with deficiency of their secretion) or to a toxemia of gastrointestinal origin, the empirical fact remains that resection of one-half or more of the hypertrophied gland substance, has been followed in numerous instances, on the testimony of competent observers, by amelioration of the constitutional symptoms, amounting, it is claimed, to a supposed cure of the disease itself in the majority of those operated upon, and in other cases to undoubted improvement, with comparatively small percentage of failures."

Thomson explains this by the fact that the thyroid hyperthrophy, being secondary to a gastrointestinal toxemia, is an injurious added factor, just as is an enlarged spleen in other diseases. He claims that good results are obtained by operation in cases which he does not consider extremely severe; that many cases are considered cured which have symptoms remaining which would, in his opinion, only justify the claim of improvement and not of cure. He further asserts that the cases are not observed long enough, since a temporary spontaneous improvement occurs often enough in many cases. He considers that surgeons find the very severe cases prohibitory to operation.

He believes that removal of the thyroid causes myxedema, but that the removal of the parathyroids causes an acute intoxication with nervous symptoms. "The parathyroids neutralize a virulent poison which reaches the nervous system through the blood. This poison is probably of food origin. The muscular tremor and the weakness are rather due to deficiency of parathyroids than to too much. The thyroid is an organ which, like the spleen, seems to be very susceptible to toxic agents acting upon it through the circulation. Even in dogs, if they are old, thyroidectomy is neither fatal nor accompanied by the usual symptoms." Kocher points out that post-operative myxedema scarcely occurs at all in elderly people.

It is certainly remarkable that the great majority of cases of well-defined or aberrant Basedow's disease are observed in women. To say that an affection of the ovaries is in a degree responsible for the genuine cases, would be going rather far. The least that we can say, however, is that women are extremely prone to morbus Basedowi, probably so because they possess ovaries.

Even if an affection of the parathyroids is an essential element in typical Basedow's disease, even if an enlarged thyroid is not the cause of the exophthalmos or of the tachycardia, and even if the enlargement of the thyroid is a secondary manifestation, we are not in a position to say that an associated hypersecretion of the thyroid is not responsible for many of the symptoms generally considered as due solely to the supposed thyroid overproduction of Graves' disease, or for cases of Basedow's disease without exophthalmos and without goitre and without tachycardia. If the ovarian secretion stands in relation to thyroid activity, as is evident from the symptoms occurring in the climacterium and after castration, there is no reason why disturbances of function on the part of the ovaries may not be responsible for other forms of "relative hyperthyroidsism," and "relative Basedow's."

Thomson explains the frequency of Graves' disease in women "by the proneness of women to gastrointestinal derangement in connection with menstruation and pregnancy and menopause." In our opinion it is just at these three stages that ovarian inactivity or insufficiency and ovarian relation to the thyroid would produce the annoying combinations of nervous symptoms, easily mistaken for hysteria or neurasthenia and resembling or actually producing aberrant forms of Basedow's disease. Even if Thomson is correct in his statement we must still reason out what makes women prone to gastrointestinal disturbances in connection with menstruation, pregnancy, and menopause. May not this proneness to gastrointestinal disturbance be the result of the metabolic changes which occur at menstruation, pregnancy and menopause, and if they are the result of these metabolic changes, then what more rational idea have we than that ovarian and thyroid interrelation, naturally of a fluctuating rather than of a stable character, produces not alone annoying and nervous symptoms but innumerable variations in the severity of the symptoms.

According to Welles the close relation between the thyroid and the reproductive functions is beyond question. The points in favor of these are the following:

(1) The greater size of the thyroid in females.

(2) The enlargement of the thyroid in menstruation and pregnancy.

(3) The tendency to develop goiter during pregnancy.

(4) Early atrophy of the thyroid after the menopause.

(5) Loss of sexual appetite in many of the thyroid diseases.

(6) Eighty per cent. of all goiters, eighty per cent. of myxedemas, and most cases of Graves' disease occur in the female.

(7) Halsted observed that bitches, who had lost part of their thyroids, when impregnated, showed evidences of athyreosis as the time of parturition approached, which disappeared soon after the litter was born.

(8) All of the pups of these litters had thyroids many times the normal size.

(9) Even in dogs if they are old, thyroidectomy is neither fatal nor accompanied by the usual symptoms. Kocher points out that postoperative myxedema scarcely occurs at all in elderly people.

The ovarian secretion has the effect of producing a congestion in the genital region. Thyroid secretion has a tendency to produce anemia

in this region, and, even without absolute proof of this fact, I have considered these two secretions to be antagonistic in their action. When the ovaries are removed at operation the vasomotor and other disturbance which come on resemble more the symptoms of hyperthyroidism, than any other condition of which we have any knowledge. In women who have not been operated on, in women at the menopause or during the climacterium, and even in women who are not near the menopause age, we frequently see annoyances of the same nature, often combined with scanty menstruation, and with the other evidences of ovarian insufficiency. Are we not justified in considering the relative oversecretion of the thyroid in them too as the pathological basis?

Perhaps in the climacterium the annoying nervous symptoms are less if the thyroid atrophies coincidentally with the ovaries, and perhaps the symptoms are more annoying if the thyroid atrophies more slowly than the ovaries. Perhaps in the climacterium the excitable cases are those with too much thyroid and the melancholy ones with too little.

Perhaps after operation the thyroid atrophies on absence of the ovaries, quickly in some cases and slowly in others, as probably happens at the normal climacterium. The patients grow stout probably because the ovaries and later the thyroid are gone, and oxygen exchange is diminished.

The probabilities are that ovarian insufficiency means relative hyperthyroidism. At any rate, even if the theory of relative hyperthyroidism is not correct, the fact that these conditions are due to ovarian insufficiency is certainly not to be questioned. The least that we can say is that the symptoms of diminished oa absent ovarian secretion and the symptoms of hyperthyroidism are sufficiently alike to express the suggestion that they are one and the same.

134 West Eighty-Seventh Street.

PNEUMONIA.*

By H. B. WEAVER, M.D.,

ASHEVILLE, N. C.

EX-MEMBER OF THE BOARD OF MEDICAL EXAMINERS; EX-PRESIDENT OF THE MEDICAL SOCIETY OF THE STATE OF NORTH CAROLINA; MEMBER OF THE BONCOMBE COUNTY, THE STATE MEDICAL, THE MISSISSIPPI VALLEY MEDICAL, AND THE AMERICAN MEDICAL ASSOCIATIONS.

Vital statistics reveal the fact that the prevalence and fatality of pneumonia are markedly on the increase. It is responsible for more deaths than any other disease. Pneumonia causes 8 per cent. of all deaths, 150,000 persons, or one every five minutes, falling annually as victims to this disease in the United States alone. Not only is the mortality of pneumonia appalling, but it is steadily increasing. While the death rate from tuberculosis, in the last two decades, has decreased 40 per cent., that of pneumonia has increased 5 per cent. Welles' latest compilation of 465,400 cases with 94,826 deaths, gives a mortality of 20.4 per cent.

Since the discovery of the cause of most of the infectious diseases, particularly smallpox, diphtheria, and tuberculosis, the decrease in mortality from these respective maladies is at once apparent and gratifying. But notwithstanding the fact that the cause of pneumonia has been established, both by laboratory research, and post-mortem findings, to be of bacterial origin, yet our latest and best methods of treatment are as unavailing and nugatory in curtailing the ravages of this disease as those which the ancient fathers of medicine taught half a century ago, when they only knew it to be a pneumonitis. In view of these facts pneumonia becomes at once the most important medical problem of the day, and furnishes food for thought for pathologist and clinician alike.

What, then, is pneumonia? How is it produced. If by the pneumococcus and other pathogenic organisms, how are they so disseminated and their virulency so increased that the disease has become so prevalent and so fatal? These are fundamental and pertinent questions that should seriously concern every anxious inquirer after the truth who wishes to see a more rational system of treatment of pneumonia.

Anatomically, pneumonia is divided into five groups, but for clinical purposes we need consider but three: fibrinous, interstitial, and bronchopneumonia.

Interstitial pneumonia, resulting usually from other inflammatory processes, is chronic in form, and will not be considered now.

The limit of this paper will only allow us to say a word in passing, in regard to bronchopneumonia, and it is this: The morbid anatomy of this disease differs from that of the croupous form, in that the circumscribed inflammatory process extends not only down the small bronchi to the alveoli, but also penetrates the deeper wall of the tubes, passing through the whole fibrous structure, and attacks the connective tissues. This interstitial inflammation of the walls of the smaller tubes, as Delafield well says, is the distinguishing characteristic between bronchopneumonia and the croupous form, the latter being a diffused exudation of inflammatory products into the alveoli and surrounding tissue without any evident change in the surrounding structure after resolution has taken place.

The difference between these pathological lesions should be carefully kept in mind in our diagnosis; for it is the difference in the nature and cause of these two inflammatory processes upon which rest the course and conduct of each disease.

Acute fibrinous pneumonia is primary, while bronchopneumonia is nearly always secondary, following the infectious diseases as a sequel, being a reinfection by the streptococci and staphylococci and not caused by the morbific agent of measles, whooping-cough, tuberculosis, or other infectious disease. In a late epidemic of bronchopneumonia, following measles, Craig demonstrated streptococci in the blood and sputum of 90 per cent. of the cases, with over 80 per cent. of mortality. Bronchopneumonia, therefore, seldom, if ever results from "catching cold," but is caused by the invasion of the respiratory tract by streptococci and staphylococci, which infiltrate the structures, causing liquefaction and destruction of the tissues, and resulting in toxemia in the diseases of childhood, and mixed infection in tuberculosis. There is also a primary form of pneumococcic origin.

Hale states that in secondary bronchopneumonia the pneumooccci are found in 75 per cent. of cases. Aufrecht says that the streptococcus pyogenes is the organism most frequently found in bronchopneumonia. In a late epidemic of the disease, following measles, among soldiers of the army, Craig found that 84 per cent. of the cases were due to secondary streptococcic infection, and of these 90 per cent proved fatal.

Next in frequency, and with greater fatality, is the bronchopneumonia following tuberculous infection. In this class of cases it is not the

* Read before the Medical Society of the State of North Carolina, 1905.

tubercle bacillus alone that does the great harm, but it is its conjoint action with the streptococcus and staphylococcus which so frequently kills the patient. It is the staphylococcus which causes the breaking down and liquefaction of the tissues; while the streptococcus is responsible for the hectic flush, nightsweats, and emaciation; it is from mixed infection, this septic pneumonia, that we have such frightful mortality.

Now from what has been said, what are the practical deductions? They can be summed up in one word—prophylaxis. And here let me insist that early diagnosis is of supreme importance. Watch your patients who are suffering from measles and whooping-cough. I know we are prone to visit our patients too infrequently in mild cases of measles and whooping-cough. But it is in these mild cases that the great danger many times lies; there is a reinfection grafted on the old, and we have a severe bronchopneumonia that might have been averted if we had early recognized the conditions.

So in tuberculosis, if the diagnosis is made sufficiently early, while it is yet tuberculosis, before there occur the characteristic lesions in the lungs, of softening and breaking down of the tissues, we can then adopt measures of prevention and cure with a greater degree of hope. But alas! This is neglected too long by both the physician and the patient, until we have pneumonia from mixed infection and the patient is hopelessly doomed.

Fibrinous pneumonia, as we know, is an acute infectious, systemic disease, with characteristic local lesions of the lungs. It is caused by a microorganism, the pneumococcus, which enters the system through the respiratory tract and blood current and produces a general disease with local manifestations in the lungs.

The route and location of pneumococci are of both pathological and practical importance. The latest discoveries in the histogenesis of the disease seem to warrant the fact that the germ enters the lungs through the lymphatic system and the blood current, passing through the bronchial branches of the vessels, by which all nutrition is furnished to the lungs, and not through the pulmonary branches. Here in a twig of a capillary blood-vessel, the pneumococcus finds a lodgment, and by its presence sets up an irritation which in turn produces hyperemia and stasis in the vessel. The walls are dilated and thinned; then occurs the first stage of engorgement. Next we have an emigration through the walls of the blood-vessels of the leucocytes with an exudation of the blood plasma and diapedesis of red blood cells into the alveoli and connective tissue. By the union of fibrinogen and paraglobulin caused by an unknown ferment, possibly the protoplasm from the pneumococci coagulation takes place and the red cells are entangled in the meshes of the fibrin. The leucocytes are found in abundance. The alveoli are now completely filled with fibrin, red blood cells, leucocytes, and granular epithelium; the stage of red hepatization, a complete consolidation of a portion of the lung is reached.

What has caused all these pathological conditions which are manifested by a sudden chill, fever, dyspnea, lowered arterial tension, and rust-colored sputum? The system here seems to be laboring under a supreme toxemia. The symptoms at this stage—just before the crisis—are out of all proportion in severity, to the gross anatomical lesions found in the lungs. But, last week I visited a patient with all these frank symptoms without the slightest signs on physical examination of the chest.

Death is the direct effect of pneumococcal activity and is not caused by mechanical obstruction, as it was thought to be under the old theory of simple phlogosis or inflammation. This fact I desire to emphasize, for it contradicts a theory which has long been held in regard to treatment, which is fallacious and dangerous.

Post-mortem findings have revealed the pneumococci in abundance, both in the blood and the coagulated exudate in the lungs. Rosenow, in 175 cases of lobar pneumonia, demonstrated pneumococci in the blood of 160 patients or 91 per cent. But in no case could he demonstrate pneumococci in the leucocytes. Leucocytosis was greatly increased in all these cases, and he was able to show a close relationship between leucocytosis and blood invasion of pneumococci. Frankel, Aufrecht, and others have demonstrated these facts over and over again, which would seem to show that the pneumococcus finds a lodgment in the pulmonary tissues, where it excites the interstitial irritation which results in an exudation of blood plasma, out of which the virulent germ elects some entity or component part, with which it unites and produces a pneumotoxin, which, being absorbed, is the prime essential virulent factor in the causation of every case of croupous pneumonia.

Acute pneumonia being a type of a toxic disease, the most important question to consider in treatment is the value of serum therapy. As in diphtheria—its only true analogue for which we have discovered a genuine antitoxin, so in pneumonia, we shall, in the near future, perfect a true antipneumotoxin. The results of late experiments along this line are indeed encouraging. Sailer's late reports from the Philadelphia Hospital, would seem to establish the fact that the treatment of pneumonia with antipneumococcic serum had passed the experimental stage, his recoveries amounting to 90 per cent. of cases treated.

The clinical type of pneumonia is varied and various, and depends entirely on the virulency of the germ and the amount of absorption of its toxin. Let us glance at a clinical picture of the crisis in this disease: You see your patient on the sixth day, he is indeed a sick man; has the same exudate in the lung as on the day previous; is still suffering from high fever, difficult breathing, low arterial tension; in fact, from supreme toxemia. You return the next day; how great the change! The patient is a well man; the fever is gone; pulse normal or nearly so; oppression in chest gone; you examine the chest, and the exudate is still there, but there is no dyspnea; he is relieved, but the exudate and consolidation have not changed. The change in the symptoms is very evident, but there is no change in the lungs. Then to what is this great change due when the crisis has been reached? Nature in her infinite resources has been guarding the patient all along these six eventful days. In her conservative course she has furnished an increased number of leucocytes which act as defenders against the bacteria in the blood, hence the increased leucocytosis in every case that recovers. Here the lowered arterial tension is favoring this natural condition.

As we have shown, the greater the leucocytosis, the fewer pneumococci are found in the blood and sputum; but in no instance have pneumococci been found in a leucocyte. At the same time the organism from the inception of the case has been manufcaturing an antitoxin which is anti-

dotal to the toxin produced by the pneumococci, whose efficiency is proved by the benign crisis. Here the system is not now laboring under a mechanical obstruction in the lungs, but from a supreme toxemia which is about to overwhelm the vital energies of the body by paralyzing the nerve centers of the heart. No, the patient does not died for want of breathing space in the lungs, but from paralysis of the vasomotor centers; in other words, dies from heart failure. If these views are correct, the treatment is indeed simple. And, as Loomis, Delafield, and Osler, the greatest clinicians of the world, have well said, as regards drugs, our treatment amounts to *nil.*

As pneumonia is a self-limited disease, the indications are (1) to support the vital powers; (2) to make the patient comfortable; (3) to control the excessively high fever; (4) to avoid depressant medicines; (5) to stimulate the heart; and (6) to neutralize the poison.

In the first place the patient should be placed upon the best possible hygienic dietetic regimen. He should be placed in a room where there is an abundance of fresh air with regulation of heat at 72°. The diet is all-important, and should consist chiefly of milk and eggs, with animal broths, avoiding the carbohydrates for fear of deranging the functions of the alimentary canal. The food should be given systematically under the physician's special instructions, as the case requires.

To relieve the pain of pleurisy and the shock which always, in more or less pronounced degree, accompanies the initial symptoms of the first stage of congestion, nothing is equal to opium in some form. Morphine and atropine hypodermically will give greater relief than any other remedy, with counterirritation of mustard plasters. Discard poultices as useless and inconvenient; cough mixtures can avail nothing but disturb the stomach. Avoid by all means the heart depressants.

Flint, in the sixties, gave the death blow to venesection; and under the present light of recent discoveries aconite and veratrum viride have no place in the therapy of pneumonia, except perhaps in the first few hours of the disease, when the physician is seldom called. All close observers freely admit that the arterial tension is invariably lowered after the first twenty-four hours. The use, then, of aconite and veratrum can only add to the burden of the heart, already laboring in consequence of the overwhelming toxemia which is paralyzing its nerve centers on the one hand, and on the other producing stasis on the venous side and lack of blood on the arterial side.

The coal tar derivatives in the treatment of high fever are to be mentioned only to be condemned. Moderate fever of 102° is a benign symptom, and should give us no concern whatever; it rather shows that the system is reacting favorably to the poison, and that the conservative powers of leucocytosis and the elaboration of an antitoxin are equal to the task of nutralizing the bacterial posion in the system. Excessive fever should, however, be controlled by hydrotherapeutic measures; the icebag to the chest or cold water by the sponge bath will usually reduce the temperature; if not, resort should be had to wrapping the patient in the cold pack; but the cold plunge is to be deprecated in most instances as unwise. Give the patient plenty of cold water to drink all the time. The next and most important question to that of food is the selection and regulation of the proper heart stimulant which is to tide the patient over the crisis. My experience is, and it is amply corroborated, that alcohol is the most potent and reliable remedy for this emergency. Its judicious use, varying according to the indications in each indvidual case, will accomplish more good than any other remedy during the second stage of hepatization, for it acts both as a food and arterial stimulant. Strychnine, also a nerve stimulant, is highly efficacious and should be used when the flagging energies of the nervous system demand it. It is often alternated with alcohol with perceptible benefit. Caffeine and camphor may both be used in asthenic cases. With quinine and digitalis in large doses as specifics I have had no experience. Some authorities recommend them highly.

We endeavor to counteract the poison by elimination, dilution, and specific medication. At the beginning of every case the alimentary canal should be thoroughly cleansed. Calomel and salts are the most efficient remedies for this purpose. Free catharsis should be kept up until nature herself comes to the relief by instituting the same process, the elimination of poisonous by-product by diarrhea. Diaphoresis should be encouraged by the timely administration of Dover's powders and potassium salts, especially the nitrate, which acts also by diluting the small blood vessels, and thereby equalizing the circulation.

Nitroglycerin is useful for the same purpose in the congestive stage. It must be given in doses of 1-100 to 1-50 grain, hypodermically, frequently repeated as it is quickly eliminated.

A great deal can be accomplished in mitigation of the disease by diluting the poison through the blood. For this purpose nothing acts so well and so quickly as the physiological salt solution, given in enema or by hypodermoclysis. Given freely it strengthens the heart and acts as a diuretic, restoring, possibly, to the circulation the chlorides upon which the equilibrium of metabolism depends.

To the specific medication in the form of an antitoxic serum we shall look with confidence in the near future, and shall see our fondest hopes realized in the perfection of a safe and efficient antitoxin for the cure of pneumonia In conclusion:

(1) Pneumonia is increasing in prevalence and fatality.

(2) The treatment is as unavailing as it was fifty years ago, because until lately the cause was unknown, and the symptoms consequently were misinterpreted, and because our treatment has been empirical and unscientific.

(3) In view of all these facts it would seem that the keynote to the whole situation can be summed up in a few words:

Prophylaxis: *Generous Support of the Vital Energies.*—If measures of prevention were more generally taught and adopted, the prevalence of pneumonia could be greatly reduced in a short while. The profession should know and the people must be taught how to prevent pneumonia. They must be informed that it is infectious; that it can be communicated from one person to another; that it is *preventable.* And how? Simply by taking care of the sputum of pneumonia patients. Instruct them not to expectorate indiscriminately on the floor or bedding. Let them spit in a cuspidor, or upon cloth, which should be immediately burned. The mouth and teeth should be thoroughly and often cleansed with an antiseptic wash. In fact all the excretions should be as seduously disinfected and

destroyed as in cases of typhoid fever. And after recovery or death in every case of pneumonia, the room should be as thoroughly disinfected by fumigations with formaldehyde as in cases of all other contagious diseases.

THE MODERN CONCEPTION OF MATTER.*

By WILLIAM DODGE HORNE, Ph.D.,

YONKERS, N. Y.

From the earliest times the study of nature has absorbed much of the thought of men. The ancient Greek philosophers sought to explain the physical phenomena which they observed first in fantastic mythical fashion, later in a logical and scientific way. Through all the development of the race man has sought to know what matter is, the laws which govern its continued existence, its many forms and the countless changes through which it passes in its infinite variety of reactions. Many theories had been advanced as to the origin and the essence of matter and the manner of its combinations, but it was not until John Dalton propounded his atomic theory in 1803 that a valid foundation was laid for that magnificent structure of physical science, which, with its grand practical achievements, has become the pride and credit of the age.

Dalton advanced the idea that every simple or elementary substance is composed of extremely minute indivisible and separate particles of absolute uniformity of mass. Different elementary substances have atoms of different relative weights, he argued, because the elements combine with each other in definite weight proportions, and this can best be explained by the hypothesis that the elements combine with each other, atom by atom. Then it was found that in certain cases an atom of one substance could combine with either one or with two atoms of some other substance, necessitating the idea that atoms had definite numbers of bonds of affinity, and that perhaps they possessed certain geometrical shapes with different poles or salient angles of affinity.

These polar attractions were very fascinating to the chemists of the first part of the last century, and it was held that all chemical compounds were composed of a positive and a negative couple, the salts, for instance, being composed of an electrically positive basic radical and a negative acid radical. This dualistic theory had to be modified, however, when it was found that highly positive hydrogen atoms could be easily replaced in many organic compounds by such strongly negative atoms as those of chlorine and bromine.

Of late years the ionic theory has come to be held as explaining the combination of the atoms in many chemical reactions. Van't Hoff showed that substances in solution exert as great a pressure as they would if they existed in the gaseous condition and occupied the same volume at the same temperature; and Ostwald and others have shown that in this condition more or less of the molecules exist in a state of electrolytic disassociation, the liberated atoms and radicals, called ions, being free to form new chemical combinations.

In regard to the substance which constitutes the elements, it was the dream of the alchemists that all matter must have had a common origin and that one elementary substance could be converted into another, and although they failed in the effort to transmute the base metals into gold, those very efforts led them to acquire a vast amount of disconnected information which later became of great value.

Mendelejeff discovered, about fifty years ago, that there exists the most wonderful and precise relation between the atomic weights of the elements and their physical and chemical properties, the whole list of known elements being divisible into groups or families whose members differ from each other by constant increments of atomic weight and by steadily increasing or decreasing intensity in chemical and physical properties. Dulong and Petit found, too, that there is a constant ratio between the atomic weight and the specific heat of all the elements. Speculating upon these facts, Sir Norman Lockyer advanced the hypothesis that all the elements were perhaps but different condensation products of one primeval gas of high attenuation, that, originally existing in nebulous condition, had cooled down and at different stages of its condensation had separated out the elementary substances as we know them. Attractive as this guess may seem, little confirmatory evidence has been deduced.

Within the last half-dozen years the great progress made in the study of radiant matter has done much to modify our conceptions of the composition of matter and a review of this line of research will best indicate the present phase of the subject.

When an electric discharge from a static machine takes place through the air a zigzag spark is seen to pass between the terminals, over a distance of a few inches; but if the discharge take place in a tube of rarified air containing, as in Geissler's tubes, air at a pressure of about 1-1000 of an atmosphere, the spark will pass through a distance of five or six feet, appearing like a glow rather than a spark and having a purplish color, varying with the nature of the gas contained. Further, the discharge visibly passes between the anode and the cathode, no matter what their relative positions in the tube may be. In 1879 Sir William Crookes investigated the phenomena produced by electric discharges in much higher vacua, his tubes being exhausted until they contained but one-millionth of an atmosphere of gas. Under these conditions the discharge appears to be entirely independent of the anode and is seen to proceed from the cathode, or negative pole, alone. The rays fall with luminous effect upon the glass *directly opposite* the cathode, which for these experiments is usually a platinum disc within the vacuum tube connected rigidly to a wire passing through the glass. These are therefore called cathode rays. A greenish light is usually thus produced, without much heat and depending for its color upon the substance upon which the rays fall and not upon the gas in the tube.

When a magnet is brought near, the rays can be deflected from their course, proving them not to be waves of light, for light cannot be deflected by a magnet.

When two cathode discs are so placed beside each other in a Crookes' tube that the rays emitted from them should be parallel it is found on passing the electric current through them simultaneously that the rays diverge, indicating that the rays are diverged from each other by an electric field, as in the previous case the rays were diverged by a magnetic field. Further, if these rays are caused to fall upon the vanes of one side of a movable wheel placed within the tube the wheel revolves indicating that the rays consist of particles of matter shot off from the negative electrode and therefore negatively electrified. Indeed the bombardment by these particles is so intense that when the rays

*Read before the Yonkers Practitioners' Club.

emitted from a concave electrode are caused to focus upon a small strip of platinum foil placed within the tube the foil is quickly raised to the red heat, and may even be melted by the heat developed by the impact of these minute particles. So great is the energy produced by these almost incalculably small particles that it has been calculated that a pound of them would raise to the boiling point in a single second the waters of a lake a thousand acres in extent and seventeen feet deep.

In 1894 Roentgen discovered that when the cathode rays are concentrated upon a platinum mirror within the Crookes tube and reflected they pass through the glass wall of the tube in a highly changed condition. They are no longer deviable by a magnet and are not capable of being reflected, retracted, nor polarized as light rays are. They cause susceptible substances like calcium sulphide and barium platinocyanide to lumanesce strongly, have high penetrating power passing easily through glass, paper, wood, flesh, and even metals in thin layers. These rays start at the point of impact with the reflector within the tube and move in straight lines. They ionize or dissociate gases when passing through them, rendering them good electrical conductors, and they also strongly affect the photographic plate.

Since Roentgen rays produce luminescence, Becquerel in 1896 undertook to ascertain whether bodies known to be luminescent when exposed to sunlight (that is, giving out light without appreciable heat) would emit penetrating rays like the Roentgen rays. He found that uranium salts impress the photographic plate whether they have first been exposed to the sun or not, the activity being a property of the uranium itself.

Following up this work Mme. Curie in 1898 investigated the relative activity of the various salts of uranium in emitting these Becquerel rays and subsequently that of the various minerals containing uranium.

She used a delicate and specially constructed electroscope in these investigations, the substances under examination discharging the same through their power of ionizing or electrifying the air between the terminals. The more radioactive the substance, the shorter the time required for the discharge. More elaborate electrical apparatus capable of detecting quintillionths of a gramme was also employed in the quantitative determinations of radioactivity.

Mme. Curie found that while in the salts the activity was proportional to the percentage of uranium contained, in the ores the activity was very different. This led her to suppose that the ores must contain some active substance other than uranium, and far more active. From uraninite she separated by chemical means an active substance which she named polonium, and continuing she finally succeeded in separating another radioactive substance, one hundred thousand times as active as uranium, which she called radium. The atomic weight of radium has been determined at 225, placing it among the heaviest of the elements. Thorium and a new element, actinium, have also been found by Schmidt and by Debierne in 1898 to emit these same Becquerel rays. These rays, besides having high penetrating power, all affect the photographic plate, are more or less deviable by the magnet, produce luminescence, and ionize gases rendering them conducting. Radium, the most active of these, is the most wonderful, at present, of all the elements. It is self-luminous in the dark, apparently from the action of its own Becquerel rays upon itself, acting as a luminescent body. Placed near other bodies it renders them in turn radioactive for a time. It burns the skin and deeply affects the tissues when brought near; it has been successfully used in the treatment of cancer, lupus, etc.; it emits a gentle heat constantly, and in spite of a constant emanation of matter in the shape of electrons Mme. Curie estimates that each square centimeter would radiate only 1.2 milligrammes in a billion years.

While the number of particles of matter emitted from even a very small amount of radium salt must be reckoned in millions per second, still they are so inconceivably minute that the specimens which have been under observation now for several years have shown no perceptible loss in weight, though tested on balances capable of indicating a part in a million. Particles so small, to produce effects so great, must be shot out with a degree of energy tremendous in the extreme.

Perrin in 1895 and J. J. Thomson in 1897 conducted investigations which proved that the Crookes rays consist of material particles which they called electrons or corpuscles, charged with negative electricity, and Thomson succeeded in measuring the mass, the electric charge and the velocity of these particles. Each one is about 1-800 of the mass of an atom of hydrogen, heretofore believed to be the smallest thing, the simplest thing in nature, and as it were, the foundation of the universe. It would take two septillion, three hundred sextillion of these particles to weigh one gramme, and they travel at rates of speed, up to 70,000 miles a second or about two-fifths of the velocity of light.

From his investigations Thomson concludes that each electron carries the same charge of electricity as does an atom in a chemically conducting liquid. The same kind of electron is obtained from every kind of matter. Electric currents are always due to the passage of these minute electric charges, passing as they do through metals, producing the phenomena of metallic conduction, through solutions, dissociating the substances dissolved and carrying the products with them to be deposited at the electrodes, and through rarified gases with almost the velocity of light. Whenever electrons are suddenly started, stopped, or made to change their direction it disturbs the ether through which they have been quietly moving and gives rise to pulses or waves constituting radiation, whether of light or Roentgen rays or other variety.

From these and further considerations based on very elaborate mathematical calculations it is now maintained that matter is composed of electricity and nothing else. Electricity here is not considered as a form of energy any more than water is a form of energy, but as a vehicle of energy, which can be moved from place to place, and whose energy must be in the form of motion or of strain. In motion it constitutes current and magnetism; under strain it constitutes charge and in vibration it constitutes light.

Sir Oliver Lodge describes the atom of matter as constituted of an individualized mass of positive electricity diffused uniformly over a space the size of the atom, perhaps spherical in shape and about one two hundred millionth of an inch in diameter. Throughout this small spherical space some 800 minute particles of negative electricity all exactly alike, are supposed to be scattered, flying vigorously about, each repelling every other and yet all contained within their orbits by the mass of positive electricity. The positive electricity is very much attenuated and constitutes, perhaps, only about one per cent. of the mass of the atom, while the negative electrons are corre-

spondingly dense, and so inconceivably small that the 800 are less crowded in their atom than are the planets in the solar system.

Atoms of different kinds of matter are supposed to be constructed in the same general manner and of the same kind of electrons, but the number of electrons in an atom are proportional to the atomic weight of the element. Thus oxygen would have about sixteen times as many electrons in its atom as has hydrogen. When the crowding becomes excessive, as in the very heavy atoms of uranium, thorium, and radium, having atomic weights well over 200, the atoms become radioactive, probably due to numerous collisions between the electrons, some of which are being constantly shot away. In like manner the atoms may be constantly emitting ether waves due to the motions of the electrons within, and so slowly undermining their own constitution. Thus atoms will occasionally collapse or divide into parts. This has been observed by Rutherford, who analyzed the radiations from radium by means of a strong magnet. Three kinds of rays were demonstrated by the effect on a photographic plate, one, of negative electrons, called beta rays, being greatly deflected by the magnet; another set called gamma rays are ethereal pulses, and are not deflected at all, while the third or alpha set are slightly repelled by the magnet, being composed of positive electrons. From the degree of deflection their mass can be calculated, and this is found to be 1600 times that of an electron, or twice the atomic weight of hydrogen. This is the atomic weight of helium, and Sir William Ramsey has observed the helium spectrum gradually to develop in a tube which contained nothing but the emanation from radium. Here, then, we have the formation of a new kind of substance, helium, next to the lightest substance known, from radium, one of the heaviest. These minute particles are thrown off with tremendous violence, causing a zinc sulphide screen to flash brightly when they fall upon it, and giving rise to heat when stopped by any obstacle.

Matter, then, appears to be composed of positive and negative electricity and nothing else. All of its properties, the newly discovered as well as the long known, can thus be explained, except gravitation; and even this is surmised by Sir Oliver Lodge to be a slight but uniform residual or secondary effect due to the immersion of negative electrons in a positive atmosphere. It is a mutual force acting between one atomic system and another which is proportional to the number of electrons in each.

Although the study of the radioactive elements has helped us to a better understanding of the composition of matter, still it leaves us unenlightened upon the cause of this spontaneous radiation.

Mme. Curie in her elaborate thesis upon the subject suggests several hypotheses in answer to the question whether the energy of radioactive bodies is generated within themselves or borrowed from external sources. It may be assumed to have been initially accumulated and then gradually dissipated as in the case of long-continued phosphorescence; it may be that the nature of the body is changing, through the particles given off, into a new body or it may be another manifestation of the force of gravitation, itself an enigma. Finally, we may imagine that space is constantly traversed by radiations yet unknown, which are arrested in their course by radioactive bodies and transformed into radioactive energy.

Be this as it may, the remarkable fact remains that within the atoms of matter reside forces of stupendous power, as much more energetic than the ordinary physical and chemical forces we are familiar with as these are stronger than gravitation.

Can we make use of this intraatomic energy? As yet only a beginning has been made, but the mind of man which has already subjugated so many of nature's forces to his use, will in time doubtless conquer this most subtle power also.

A CASE OF TYMPANIC AND MASTOID CHOLESTEATOMA; EXTRADURAL ABSCESS; SINUS THROMBOSIS; PROLONGED PYEMIC TEMPERATURE WITHOUT METASTASES; RECOVERY.

By DONALD M. BARSTOW, M.D.,

NEW YORK.

VISITING SURGEON, NEW AMSTERDAM EYE AND EAR HOSPITAL; ASSISTANT AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY AND ST. BARTHOLOMEW'S CLINIC.

The patient, a boy, twelve years of age, came under my care on January 26, 1905. He gave the following history: About ten years ago he had scarlet fever, in the course of which he suffered with pain in, and discharge from, the left ear. On his recovery the ear failed to clear up, and ever since then he has had more or less discharge therefrom. One year ago he had an attack of pain in the ear, with some fever and a swelling over the mastoid region. The swelling was incised, and some pus evacuated. The wound healed in the course of a few weeks, the otorrhea continuing. One week ago he began to have renewed pain in and behind the ear, with increase of the discharge. For the last three days he has had pain in the left occipital and parietal regions, with feverishness but no chills.

Physical examination.—The boy is pale, his facial expression somewhat drawn and anxious. Temperature 103°, pulse 100. The left tympanic membrane shows a large perforation, through which a foul-smelling pus is slowly discharging, mixed with small masses of cheesy consistency. There is marked tenderness over the entire mastoid region. Over the region of the antrum there is a linear scar about one inch in length. The skin here is slightly reddened. There is no edema.

Operation, January 28, 1905.—The mastoid was opened after the manner used by Dr. Whiting. The entire mastoid apophysis was found softened and destroyed, the cells full of soft, dark-colored granulations, pus exuding from the antrum. The antrum attic and adjacent region were full of foul-smelling cholesteatomatous matter. The inner table over the sigmoid sinus was softened and dark, and on scraping it away about half an ounce of foul-smelling pus escaped. The subjacent dura was covered with dark-colored, flabby granulations. This extradural abscess was found to cover the entire sinus as high as the knee, and to extend forward and backward, covering an area about the size of a twenty-five-cent piece. As the patient's pulse was very feeble, and as the sinus appeared to be pervious, it was determined not to open it. The posterior wall of the bony meatus was chiselled away, thus throwing antrum and tympanum into one cavity, making a radical mastoid operation, and the tympanum was carefully curetted out. A Whiting flap was cut from the soft parts of meatus and fastened in place with catgut

sutures. The wound was packed with iodoform gauze and the patient put to bed.

Next morning (January 29), the patient was very comfortable, his temperature being 99.8. At 12:30 P. M. he had a severe chill lasting fifteen minutes, followed by a temperature of 104.6°. At 9 P. M. he had a second chill; temperature at 9:30 P. M., 106°. He then went to sleep and slept till 6 A. M., January 30. At 7 A. M. he had a third chill, followed by a temperature of 105.6°. It was evident that there was thrombosis of the sigmoid sinus, and that a second operation would be necessary. The patient was therefore prepared, and at 11 A. M., January 30, assisted by Drs. Cook, Steel, and Moe, I removed the dressing and opened the sinus. A soft gray clot was found, extending from knee to bulb. On carefully scraping this away, free bleeding was easily established from both lateral sinus and jugular bulb. The first blood from the bulb was mixed with pus. As the hemorrhage from the bulb was so free, it was not thought necessary to tie off the jugular vein, therefore the cut ends of the jugular were plugged with iodoform gauze and the wound packed with the same. The patient came off the table in remarkably good condition, with a pulse of 86.

For the next five days the patient remained comfortable, the temperature ranging between 99.5 and 102.8, and the pulse from 88 to 108. On February 4,

at 6 A. M., he had a slight chill, followed by a temperature of 104°, pulse 120. Temperature remained high all day until 6 P. M., when it dropped to normal, but during the evening it again rose to 104. This pyemic temperature continued until February 6, when it was decided to ligate and remove the jugular vein. This was done by the usual incision, extending from in front of the lower end of the first incision to the suprasternal notch. The sheath of the vessels was opened, and the vein separated from the vagus nerve, tied in two places, and cut. The facial vein was also tied off and cut, and the entire jugular vein dissected out. The wound was packed with iodoform gauze and the patient returned, in very fair condition, to bed.

For twenty-four hours after the operation on the jugular vein the temperature remained normal or sub-normal. During the afternoon of February 7, however, it began to rise, and at 8:30 P. M. it reached 105.4°. From this time on his temperature ran a typically pyemic course, going from sub-normal to 105° or over every day. The boy was cerefully examined every day for metastatic abscesses, but none were found. He had on one occasion a few very indefinite subcrepitant râles in the right chest behind, but the râles were unaccompanied by cough or accelerated respiration, and they disappeared in twenty-four hours. The wounds healed as rapidly and kindly as if there had been no infection, and the ligature came away from the lower end of the jugular vein on February 20, just fourteen days after the operation. The boy's appetite was excellent, and he was allowed a liberal diet, to which he did ample justice. A week later the picture remained the same Blood counts showed a tremendous leucocytosis, and on one occasion streptococci were demonstrated in the blood. On March 3, for the first time since the ligation of the jugular, he had no chill, and his temperature ranged from 99° to 102.5°. The three days following (March 4, 5, and 6), were similarly free from chills, and showed a like range of temperature. At midnight, March 6, however, he had another chill, followed by a temperature of 105°. The temperature quickly came down to the normal, however, and remained so until late in the evening. About 11 P. M. he suddenly became delirious and cyanotic, his pulse was uncountable, and his temperature, taken in the axilla on account of his restlessness, went to 107.8°. The delirium and cyanosis lasted about an hour. At 12:30 A. M., March 8, his temperature was 105°, at 3 A. M. it had fallen to 100°, and at 7.45 A. M. it was 97.2, his pulse was 96, his head was clear, and he was demanding food and showing no apparent ill effects from his ebullition of fever. His temperature remained low for two days, but again on the 12th, 13th and 14th he resumed the old program of daily chills, although comparatively moderate temperatures (the maximum being 105.6°) followed them. There being still no signs discoverable of metastatic abscess anywhere, it was suggested by one consultant that there might be trouble in the torcular end of the cut lateral sinus. Acting on this suggestion, on March 16 I reopened the posterior wound, uncovered the lateral sinus, and opened it. Free bleeding was obtained at the first cut, indicating that the sinus was clear. The wound was plugged, and the patient was returned to bed, in better condition after this fourth operation than any after any one of the preceding three.

Although nothing was found to justify the last operation, yet its effect appeared to be rather good. He had no more chills or chilly sensations, and he seemed to gain strength more rapidly. His temperature, also, showed a lower range. On March 23, at 5:30 P. M., without any chill, his temperature reached 105.2, but it dropped rapidly to normal, and on March 24 his condition was so good that I allowed him to sit up in bed for an hour. There was no further trouble from this time on. The next day he sat up in bed all day, his temperature ranging from 97.2° to 99.5°. On the 26th he was allowed to have his clothes on, and on the 29th he was discharged from the hospital and taken home by his parents.

The subsequent history of the patient presented no unusual features. He came regularly to the dispensary three times a week for dressing, and on June 15 his ear had completely dermatized, his other wounds were all healed, and he was discharged from further treatment.

The interesting and unusual features of this case may be summed up as follows:

Time in hospital, eight weeks and four days.

Time during which pyemic temperature lasted, seven weeks and five days.

Metastatic abscesses, none.

Number of chills, thirty-nine.

Highest temperature, 107.8°, in axilla.

Lowest temperature, 96°, in mouth.

Range of temperature, 11.8°.

527 Madison Avenue.

SOME NOTES ON THE CEREBROSPINAL FLUID.

By N. A. PASHAYAN, M.D.,

KINGS PARK, N. Y.

Lymphocytosis in the cerebrospinal fluid has been observed in a number of conditions such as syphilis and chronic alcoholism; but special diagnostic value has been accredited to it in two diseases—viz., general paresis and tabes. With the object of inquiring into the constancy of this sign in paresis and also into its occurrence in other mental affections, a number of patients were selected and a cytological examination of the spinal fluid made.

The following comprises the list: General paresis, all types, 27; Major epilepsy, 24; Infantile cerebral palsy with epilepsy, 2; Primary lateral sclerosis with imbecility, 2; Hebephrenia, 13; Katatonia, 8; Manic-depressive insanity, 7; Chronic alcoholic deterioration, 7; Paranoiac states, 7; total, 97.

The diagnosis of paresis in the cases examined could be considered reasonably certain, being based on well-defined somatic signs and mental symptoms. The findings may be tabulated as follows:

Type of Disease and Remarks.	Number of Lymphocytes.
1. Stuporous dement	282
2. Mildly exalted	185
Same case on another occasion	151
3. Marked expansive ideas	162
4. Depressed	133
5. Cerebrospinal type	129
6. Maniacal	79
7. Depressed, rapidly advancing deterioration	52
8. Demented	51
9. Maniacal excitement	42
Same case during remission	50
10. Demented	48
11. Demented	46
12. Expansive rapid mental and physical decay	33
13. Markedly hypochondriacal	32
14. Demented	29
15. Expansive type, colored with persecutory ideas	24

16. Demented	22
17. Demented	20
18. Maniacal excitement	17
Same case in remission	8
19. Demented	15
20. Expansive type	15
17. Demented	29
21. Expansive type, with apparent arrest of the disease	12
Same in different tapping	9
22. Hypochondriacal	10
23. Demented	4
24. Grandiose ideas	2
25. Demented	0
26. Depressed—prolonged remission	0
27. Expansive type	0

In sixteen of the cases the increase of the lymphocytes may be considered marked, in five moderate, in three doubtful, and in three negative. The disease process was active in the two of the negative findings, while the third was in a state of prolonged remission. Of the doubtful number one was in a condition of mental habetude after a period of maniacal excitement.

The type or the stage of the disease did not seem to have any special bearing on the degree of the cellular reaction. The highest count was seen in a stuporous dement whose physical health was good. Only seventy-nine lymphocytes were found in a case of continuous psychomotor agitation, at times bordering on delirium. No. 12 in the above list, while undergoing a rapid mental and physical dilapidation, exhibited no more than thirty-three cells. On the other hand, there were obtained 129 lymphocytes in a patient suffering with the ascending or cerebrospinal type of the disease, who was in splendid health physically and the mental symptoms were limited to slight amnesia for recent events, some morbid euphoria, and boastfulness. During the height of maniacal excitement in one case the lymphocytes numbered forty-two, while a few months later, in a period of remission, fifty cells were found.

No lymphocytosis was discovered in major epilepsy with one exception. On two different tappings twenty-two and twenty-six lymphocytes respectively were found. The patient had been an inmate of the institution for six years and suffered with epilepsy since childhood. There were no physical signs pointing to tabes, paresis, or any other organic disease. Any residual signs of luetic infection were wanting. It might be added, however, that he has had for a number of years psoriasis of the scalp.

The findings were negative in all cases of hebephrenia—7, 5, 3, and 2, were the only cells encountered. Similarly no increase of lymphocytes was seen in katatonia. Every one of the latter group was characterized by stupor, negativism, and marked muscular rigidity.

Manic-depressive insanity was not accompanied by lymphocytosis. The seven cases included only manic and mixed phases of the psychosis. In none of them did the number of cells exceed two.

The seven cases of chronic alcoholic deterioration were quite typical of their class, but in none of them more than one or two lymphocytes were met with.

No increase of cells was noticed in any cases of the organic nervous diseases nor in any of the paranoiac states.

Six of the cases with negative findings in the above list, two being paretics, gave a history of having had syphilis. In five of them corroborative physical signs were still present. Several years had elapsed, however, since inoculation took place, the most recent one antedating five years.

In estimating the number of the lymphocytes the plan adopted differed in principle from those generally recommended. The patient lay invariably on a table on the right side, head and knees drawn to the chest. Within five or ten minutes after a subcutaneous injection of thirty minims of a 4 per cent. cocaine solution, a long, narrow aspirating needle was inserted between the first and second lumbar vertebræ close to the spinous process. The fluid was collected in sterile tubes and soon after and without centrifugalization the amount of the lymphocytes estimated. For this purpose a Thoma-Zeiss hemocytometer was employed and the number of cells found in 4,000 squares taken as the index of the lymphocytosis present. The specific gravity of the lymphocytes being practically identical with that of the fluid, cellular distribution, and hence their estimation, must needs be uniform. Ten chamberfuls of the hemocytometer being counted, the result should indicate if any increase of lymphocytes existed. The figures above given were obtained in counting the unprecipitated fluid in 4,000 squares.

Fluids containing erythrocytes were discarded. Where any appreciable number of lymphocytes were met with, the specimen was centrifugalized and the deposit transferred on slides, dried, fixed, and stained as ordinarily done with blood. It was seen that large lymphocytes averaged 70 to 80 per cent. and small ones 20 to 30 per cent. Occasionally a few transitional leucocytes were also seen. Polymorphoneutrophiles were absent.

The total amount of the fluid withdrawn varied in individual cases, the average being 2 and 6 c.c.

The position occupied by all the patients being the same, it was remarkable to see how much variation in the degree of tension existed. In some hardly one drop every 5 or 10 seconds could be obtained, while in others as soon as the membranes were punctured there was a gush, a continuous jet streaming for one minute or longer. As a general rule two drops per second was the rate at which the fluid would escape. Talking or any other effort would always accelerate the flow. No special relations seemed to exist between the psychosis and the degree of tension. Paretics as a class appear to have high tension, but there were a good number of exceptions to this. Among those having high tension were epileptics, manic-depressive cases and precocious dements. The highest as well as the lowest tensions were observed in epileptics—in the latter case the fluid was almost viscid.

Under cocaine anesthesia very little if any pain was experienced by the patients. Eliminating all complaints referable to pain or fear, there were still manifested physical and psychic symptoms that can be conveniently classified as immediate and later effects. Among immediate effects pallor, acceleration and irregularity of pulse, but, over and above all, dyspnea—a genuine "air-hunger" and difficulty of inspiration should be mentioned. A few cases became talkative and emotional. One patient in particular, while on the table was calm, suffered no discomfort, and was conversing pleasantly. As soon as he was put to bed he became confused, garrulous, and soon passed into a state of delirium lasting about ten minutes. He complained of great thirst and consumed nearly a gallon of water within the next few hours.* A few complained of tem-

*In order to exclude the possibility that the delirium might have been due to the idiosyncrasy of the patient to cocaine, it was intended to give him the same amount of the solution hypodermically without lumbar puncture, but unfortunately he left the hospital before this was done.

porary parethesias in the legs, such as numbness and pins and needles. Chronic alcoholics seemed more susceptible to immediate effects than any other class.

The later effects consist principally of headache, vertigo, nausea, vomiting, and a general malaise. These make their appearance from two hours to two or three days subsequent to tapping. Vertigo and headache are very distressing and may persist for a week or more. Those having high tension seem more predisposed to them. On the other hand, paretics suffer very little from these after-effects.

Every possible precaution for surgical cleanliness was taken, and in a number of over 175 tappings no focal or systemic ill-effects from this source were developed.

To summarize: Of 27 cases of general paresis a marked increase of lymphocytes was seen in 16, moderate one in 5, doubtful in 3, and negative in 3. Lymphocytosis was absent in 7 chronic alcoholics, 6 old syphilitics, 25 epileptics, 13 hebephrenics, 8 katatonics, 7 manic-depressive cases, and 7 paranoiac states.

Kings Park State Hospital.

SURGICAL RINGS.

By H. A. SHAW, M.D.,

SEATTLE, WASH.

Through the medium of this journal I wish to bring to the notice of the profession a surgical device which other local surgeons as well as myself have found both time-saving and efficient.

The device consists of a pair of steel rings with a small segment cut out. They fit upon the second phalanx of the index fingers, with a denticulated plate upon the inner side of each ring, as seen in figures 1 and 2.

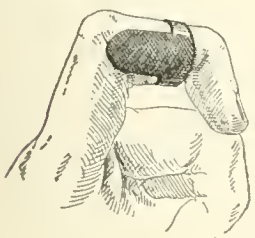

Fig 1.

Fig. 2.

The primary object of the device is to enable the operator to go back to first principles, and use his fingers instead of forceps, needle holders, etc.

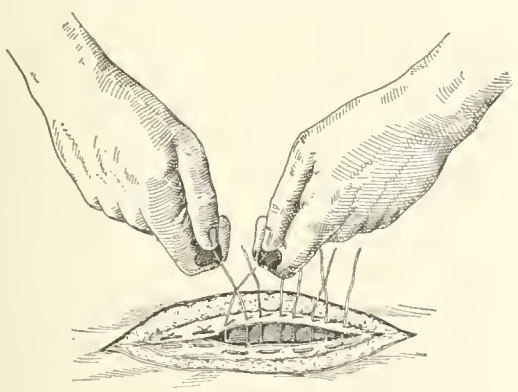

Fig. 3.

1. Its first and most important use is in tying sutures and ligatures. In this case the main advantages are that it is ready for instant use and does not weaken the suture or ligature material, as forceps does, and also avoids cutting of the fingers and consequent infection (Fig. 3).

2. It enables the operator to separate adhesions with the fingers without the aid of forceps, gauze,

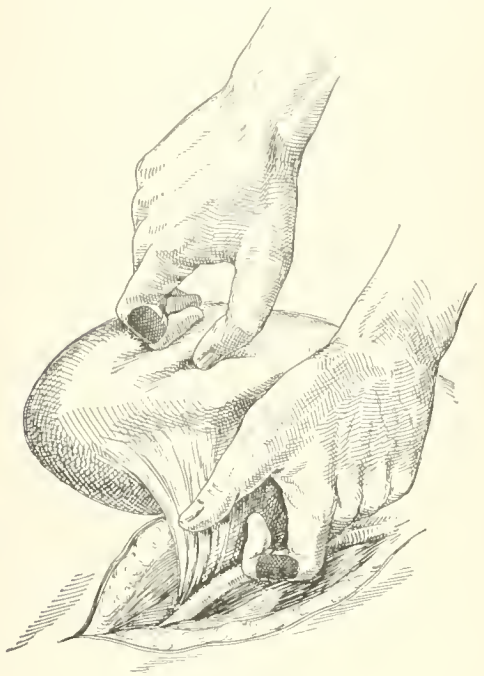

Fig. 4.

etc., with the least amount of injury to the tissues, being especially valuable in separating the hernial sac from the cord, and in varicocele (Figs. 4 and 5).

3. In grasping and retaining tissues, it is much handier and produces less injury than tissue forceps.

4. In the manipulation of the needle, both as a

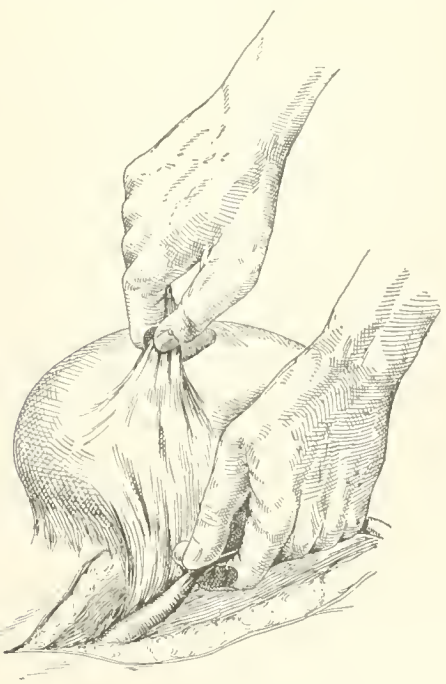

Fig. 5.

holder and as a guide in directing the point of the needle among important structures.

5. Lastly, it enables the operator to handle with ease slippery viscera, as intestines, etc.

It may be said in conclusion that these rings in no way interfere with the action of the fingers.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, February 10, 1906.

THE TREATMENT OF SHOCK.

VASOMOTOR relaxation has long been recognized as the important factor in the production of shock, but the researches of Crile during recent years have undoubtedly added renewed interest to the subject. The question of treatment has also become pretty well crystallized, and prophylactic measures occupy a position of greatest importance. For the shock itself, physiological salt solution and adrenalin have come to be regarded with the greatest degree of favor. Strychnine has largely been employed as a stimulant in this condition, but its value is questioned by many, as it has been shown by animal experiments that this drug exerts little or no influence in raising the blood pressure, which is the essential feature of the treatment. An interesting symposium on this subject is presented in the pages of the December number of the *Therapeutic Gazette,* in which the opinions of a number of leading surgeons have been included.

W. W. Keen has now given up entirely the use of strychnine in shock, basing his change of opinion as to the value of the drug on Crile's researches, and he is very well satisfied with adrenalin, which he has substituted for the former. E. E. Montgomery lays particular stress on the preventive treatment of shock, but when it does occur he advises the injection of a single large dose of strychnine (gr. 1/20-1/5) as a cardiac stimulant, and, in addition, hypodermoclysis or intravenous infusion of a one per cent. solution of sodium chloride containing adrenalin. Repeated doses of strychnine are cumulative, and he therefore advises subsequent injections of some aseptic ergot preparation as an excellent means for increasing the contractile power of involuntary muscular fiber, relying on this as the most effective agent against shock, next to salt solution. Edward Martin favors strychnine as a tonic before operation, but during and after the same he has abandoned its use, particularly in the case of pure shock which is primarily due to trauma and can be helped neither by drugs nor by hypodermoclysis. The latter, in his opinion, is useful merely in favoring elimination, and should be given so slowly as to be immediately absorbed. The only drug which seems to have any effect at all in desperate cases is adrenalin, and to be effective this must be given intravenously and in extreme dilution (1:20,000). When hemorrhage complicates the case, intravenous infusions are of value only if given slowly and repeatedly.

Da Costa is convinced that Crile is correct in his views as to the futility of strychnine in the treatment of shock, as it merely hurries the circulation without strengthening it, and its effects are only transitory. Adrenalin in small amounts hypodermically is also transitory in its effects, but when given intravenously in salt solution and very slowly, it is a remedy of the highest importance. La Place contends that the slow absorption which has been observed to occur when strychnine is given, in a measure explains the inefficiency of the latter in cases of deep shock, and also accounts for the large doses tolerated when the circulation is thus depressed. Restoration of the circulation is always the most important consideration, and La Place believes that this may be most effectively secured by the application of the electric current. Notwithstanding the experimental evidence adduced against strychnine, H. A. Hare favors it as stimulant of the entire organism, and although it may have been relied upon too much in the past, he believes that it should not be cast aside entirely, but be used in connection with the other measures advocated for the treatment of shock.

DOCTORS AND POLITICS.

THE opinion has been expressed frequently in the editorial pages of the MEDICAL RECORD that it would be to the benefit of the general public and of the medical profession itself, if medical men took a more active part in politics. There is no need for a doctor to become what is known as a politician; in fact such a course would not serve the purpose of advancing the interests either of the community at large or of the medical profession—indeed, the effect would be rather the reverse. It is fairly well understood that the politician pure and simple regards politics as a profession or game at which he endeavors to gain a fortune, or at any rate a livelihood. He is fighting for his own hand or for the advantage of the organization to which he belongs.

There is every reason, however, that the medical man should evince a certain amount of concern in those matters which relate to medicine or sanitation, and use his influence to promote the health of the people and to safeguard the interests of his own profession. It is notorious that bills are continually being brought forward or passed in the legislatures of every State of the Union that menace public health, and have been designed with the view of injuring the medical profession. There can be no doubt that the doctor can, if he will, wield an immense amount of influence. He is, perhaps, by virtue of his calling, in more intimate touch with all sorts and conditions of men than is the member of any other class. The way, therefore, in which the medical man can do most good is by educating those with whom he comes into close contact to a sense of the necessity of possessing sound sanitary and medical laws, and by teaching them that such laws are not advocated solely for the selfish reason that they will conduce to the advantage of his own profession. This is essentially a material age, perhaps the most material age that has been ever known, and the United States is by no means the least commercial country of the world, the consequence being that almost any bill introduced by a medical man, or any opposition advanced by the medical profession to legislation favoring quacks, Christian Scientists, and illegitimate practitioners of every description, is immediately put down by an in-

considerate public to the doctor's peculiar care for number one. Of course we do not insist upon the proposition that the members of the medical profession are one and all unselfish and absolutely without guile. Such a statement would be too manifestly absurd, for there are some very wily and by no means guileless politicians in our own ranks. But the assertion is made deliberately that the distrust with which medical measures are generally regarded is unfair to an in the main honorable and generous profession, and will react injuriously on the heads of the sceptics.

What is really required is a better understanding between the people at large and the doctors, and it is plain that no one is better qualified to remove suspicion than the physician himself. A political missionary medical man has a wide field in which to work, and by assiduous zeal, combined with discretion and straightforwardness, should succeed in making many converts. Only convince a man that your intentions are honorable, and above all that their consummation will be to his physical and material good, and he will undoubtedly be upon your side. In the *Lancet* of January 13, medical men and the British general election are considered editorially. Our London contemporary takes the eminently correct view that medicine and partisanship in politics should be completely divorced. It is pointed out that medical men who are candidates for election to Parliament are not going to the poll as medical men, but as members of the particular party to which they may have given their adherence. Notwithstanding the expression of these rational sentiments, our contemporary takes occasion to draw attention to the fact that it is in a high degree desirable that the medical profession should be well represented in Parliament, if only for the reason that "politics, not only domestic politics, but foreign politics, revolve more and more around questions of public health." To give an instance, which applies with equal, if not greater, weight to the United States than to Great Britain, enormous numbers of poverty-stricken, diseased, and persecuted men and women have been leaving Russia in order to seek a haven of rest in a free country. The majority of these have made their way to this country, either to be rejected or to be allowed to enter, but a substantial proportion of the horde has been landed in British ports. The *Lancet* argues, and rightly, we think, that the statesman of to-day may at any moment find himself in need of expert medical advice, and that therefore the medical profession should be adequately represented in the national legislature. However, the argument that medical men should interest themselves in politics is so self-evident that it would be superfluous to continue to press the point. Up to the present time the American physician has shown himself lethargic and languid so far as politics are concerned. He has acted as if he had no part nor parcel in the regulation of matters which most assuredly affect him closely. It is time that the medical profession of the country should come to a realization of the situation, and should resolve, by every means in its power, to forward the welfare of the entire community and to conserve its own interests. Such a result will not come by sitting with folded arms and watching the progress of events.

A PATHOLOGICAL FACTOR IN A CASE OF MORTON'S DISEASE.

Since Morton, in 1876, first recognized and described metatarsalgia as a disease *per se*, a great diversity of opinion has existed with reference to its etiology. As anatomical changes were hard to trace in connection with this complaint, the latter was quite generally regarded as of nervous origin. Morton himself sought to find an explanation for the characteristic pain in some abnormal configuration of the arch of the foot, due to tight shoes or trauma. In a large number of cases, infectious diseases, particularly malaria, gonorrhea, and influenza, were considered to have some bearing on the production of metatarsalgia, in others localized toxic or inflammatory processes were accused. Traumatic and inflammatory deposits have also been thought of as etiological factors, although true tumors in connection with the disease have rarely ever been observed. A few instances of calcified enothelioma, fibroma, and lipoma have been noted, but the connection between these and the attacks of pain could never be clearly traced. Furthermore, in most cases operated upon no pathological changes could be detected in either the neighboring joints or the affected nerves.

The uncertainty which apparently exists regarding the etiology of Morton's disease renders the finding of a definite pathological lesion, even if thus far in only a single instance, of considerable interest. Pochheimer (*Zeitschrift für Chirurgie*, Vol. 80, No. 3) had under observation a young woman who developed a typical case of metatarsalgia after having suffered repeated injuries to her foot. Subsequent examination disclosed a number of nodules under the skin, scattered along the flexor surface of one of the toes. An operation undertaken for the relief of her symptoms showed that these nodules were distributed along the course of the nerve supplying the digit, and on microscopical examination they proved to be fibrosarcomata. They were apparently derived from the flexor tendon, its sheath, or the plantar fascia. The pain was probably due to direct pressure exerted by the tumors, and no nerve elements could be found in any of them. The lesion here referred to is extremely rare, however, and does not by any means afford sufficient evidence to warrant our attributing all cases of Morton's disease to this source; yet it clearly demonstrates how important and necessary it is to bear in mind the possibility of latent tumor formation even in cases of seemingly purely neurotic conditions in the foot. One should not be satisfied in any given case with an explanation which attributes the pain to a simple inflammatory process, but when sufficient doubt exists an exploratory operation, in order to determine the true condition of the parts, would be justifiable. Morton's disease is unfortunately not an uncommon condition, and we would doubtless know more about it if this suggestion of Pochheimer were more frequently acted upon.

Relief of Intercostal Pain by Sterile Water Injections.—Localize the pain by pressing deep into the intercostal space, then inject a syringeful of sterile water into the tissues in the vicinity of the nerve. Complete cure has followed this procedure when morphine gave only temporary relief.—J. J. Reid.

Etiology of Congenital Dislocation of the Hip.

The unusual prominence given to this subject within recent years lends particular interest to the numerous theories which have been brought forward to account for the production of this deformity. Broadly speaking, these may be grouped into two great classes—in the first, the luxation is ascribed to some error of growth or development; in the second, the condition is attributed to some abnormal attitude of the fetus in utero. All other attempts to explain the deformity, including trauma during pregnancy or labor, relaxation of the joint ligaments, articular hydrops, localized muscular paralysis, etc., have failed to withstand criticism. Since the lesion has become better understood, the number of reported cases has greatly increased, and among the interesting points noted in studying this mass of clinical material is the fact that the deformity is often associated with others in the body, which in most instances depend on some mechanical influence. Among these are torticollis, pes varus, genu recurvatum, and a number of others. Paul Ewald, in an article in the *Deutsche Zeitschrift für Chirurgie,* Vol. 80, Nos. 3 and 4, suggests that there is no good reason why we should not ascribe the congenital hip dislocation to the same factors which bring about the other deformities mentioned. It is believed that insufficiency of liquor amnii, together with anomalies in the form and position of the uterus on the one hand, and in the presentation and position of the fetus on the other, have an important bearing on the production of the deformities mentioned, and it is not unreasonable to assume that they exert an equally important influence in the production of the luxation under discussion. That no inherent error in development exists which tends to produce a congenital dislocation of the hip, seems fully proven by the fact that after successful reposition of the femoral head, an acetabular cavity will form, even after a period of one and a half to three years has elapsed. This certainly could not occur if any inherent developmental error existed in these parts. It has also been shown by animal experiments that a flattening of the acetabular cavity will follow either a resection of the head of the femur or any means taken to prevent a close approximation of the latter to the acetabulum. We may imagine that this condition may readily enough be reproduced in a fetus which is made to assume an abnormal attitude by anomalies in the uterus or the maternal pelvis.

Protective Inoculation Against Typhoid Fever.

An interesting contribution to this all-important subject is contained in a report by the commander of the German troops in Southwest Africa, where the procedure had been employed on a fairly large scale and in a systematic manner, published in the *Archiv für Schiffs- und Tropen-Hygiene,* Vol. IX. No. 12. Of 424 patients with typhoid fever under observation, there were 100 who had previously received from one to three injections of the Pfeiffer-Kolle serum. The time which elapsed between the injections and the onset of the disease was not always accurately known, but in no instance could it have exceeded nine months. It was found, however, that in the worst among the inoculated cases in this series, the patient had been taken ill soon after vaccination, and apparently the protective action of the serum required at least three weeks or longer for its proper development. Several features of interest are presented by a comparison of the course of the disease in the non-vaccinated and the vaccinated subjects. In the former class of cases, to begin with, the mortality was 11.1 per cent.; in the latter, 4 per cent. It was also observed that although mild cases were found among the non-vaccinated patients, these seemed to be more prevalent in the other group, particularly as regards the toxic symptoms. Thus, there was little headache complained of, no sensory disturbances of moment, and slight cardiac involvement, although the other evidences of the disease, such as splenic enlargement, the characteristic eruption, and the pea-soup stools, were present. The fever ran a much shorter course in the inoculated patients, and did not reach an equal height. Recurrences were very infrequent. Final conclusions on the value of protective inoculation in typhoid fever cannot as yet be formulated from the observations which have thus far been published, but they certainly afford us a favorable outlook for the future. An absolute protection against the disease has not been attained, but there can be little doubt that its effects have been ameliorated in those who have subjected themselves to protective inoculation, and this protection, moreover, seemed to be measured by the number of inoculations. If the method has not been sufficiently developed for general application in civil medicine, there should be no question as to its further trial in armies, in which we have come to fear diseases of this class more than wounds received in battle.

News of the Week.

A Reception to Baron Takaki will be tendered by the New York Academy of Medicine on February 15, after the regular exercises of the meeting. The program of the evening will be: A paper on "Arterial Sclerosis of the Viscera," by Dr. Harlow Brooks; a paper on "Arterial Tension," by Dr. Theo. C. Janeway, and "Remarks on Medical Schools in Japan," by Baron Takaki.

The Dirty Streets of New York.—Bird S. Coler, president of the Borough of Brooklyn, recently made an attack, in a published interview, upon Commissioner Woodbury for his neglect to clean the streets, and is quoted as saying that he is the "most incompetent official in the city." "The condition of the streets and the public dumps here," Mr. Coler is reported to have said, "is simply disgraceful. I have taken trips through different sections of the borough and have found the streets littered with papers and rubbish and no evidence that a real effort had been made to keep them clean. I consider Major Woodbury thoroughly incompetent. About all he prides himself on, apparently, is that his horses are in stables that are as handsome as castles. Our streets are dirty beyond endurance and Woodbury does nothing." There is certainly no question as to Dr. Woodbury's failure to keep the streets clean. Even under Nagle, of scented memory, they were hardly so filthy as now.

Rockefeller Institute Scholarships and Fellowships.—The Rockefeller Institute for Medical Research purposes to award for the year 1906-07 a limited number of scholarships and fellowships for work to be carried on in the laboratories of the Institute in New York City, under the following conditions: The scholarships and fellowships will be granted to assist investigations in experimental pathology, bacteriology, medical zoology, physiology, pharmacology, and physiological and pathological chemistry. They are open to men and women who are properly qualified to undertake research work in any of the above mentioned subjects and are granted for one year. The value

of these scholarships and fellowships ranges from six hundred to one thousand dollars. It is expected that holders of the scholarships and fellowships will devote their entire time to research. Applications accompanied by proper credentials should be in the hands of the Secretary of the Rockefeller Institute Dr. L. Emmet Holt, 14 West Fifty-fifth Street, New York City, not later than April 1, 1906. The announcement of the appointments is made about May 15. The term of service begins preferably on October 1, but, by special arrangement, may be begun at another time.

Quarantine Regulations.—Members of a special committee selected by the Southern Representatives and Senators have agreed on a bill relative to quarantine matters which has been submitted to a delegation from the States especially interested. The object of the bill is to provide for wider jurisdiction of the Public Health and Marine Hospital service, and to prevent the introduction into Southern ports of yellow fever from Central and South American countries. Among other things the measure appropriates $500,000 for the purpose of acquiring suitable places for quarantine grounds and anchorage for vessels at such points as may be best suited to prevent the introduction of yellow fever. This sum is placed at the disposal of the Surgeon-General in part also, to prevent the importation of the disease and its eradication in case it is introduced. A special quarantine commission, promoted by the Union Fruit Company and the New Orleans Board of Health and comprising many Southern health officers, has been visiting Panama, Colon, and other places for the purpose of studying local conditions and forming practical quarantine regulations for the future.

Pure Food Laws.—Eighty cases of alleged violation of the pure food laws have lately been sent to the Attorney-General for prosecution. The New York State Department of Agriculture will increase the scope of inspection of foodstuffs. Heretofore, candies, preserves, syrups, and flavoring extracts only have been held up to tests, but now flour, meats, and breakfast foods are also to be analyzed. A bill to define natural, pure, artificial and carbonated wines, and to prevent misbranding, adulteration and imitation of wines, is now before the Committee of Ways and Means at Washington.

State Health Report.—The annual bulletin of the State Department of Health shows a total of 137,059 deaths reported last year. This made a death rate of 17.4 per thousand population, or about the average of the last five years, against 18.2 in 1904. There was a daily average of 376 deaths, against 380 in 1904 and 350 in 1903. Pneumonia was the cause of death in 14,157 cases, against 13,531 in 1904, and 9,000 in 1903. Pulmonary tuberculosis caused 10 per cent. of the deaths. The mortality from cerebro-spinal meningitis was 2,566, against 1,700 in 1904, and the average in former years, 550. Scarlet fever, after four years of high mortality, has suddenly decreased by half.

Aid for Needy Patients Discharged from State Hospitals.—At a conference held in Albany on January 31, representatives of the Charities Aid Association of New York City, members of boards of managers of the various State hospitals, the superintendents of State hospitals and the State Commissioners of Lunacy, agreed upon a plan for after-care of needy patients who are discharged from insane hospitals in this State as cured. The plan is to be carried out by the Charities Aid Association, if it will undertake the work as requested by a resolution adopted by the conference.

New York News via London.—The *British Medical Journal* announced a few weeks ago that the election of a Tammany Mayor of New York had resulted in the dismissal of our efficient Health Commissioner, Dr. Darlington. In its next issue, however, our contemporary corrected this statement, and informed its readers that "Dr. Darlington has been reappointed Commissioner of Health of New York City at a salary of 7,500 dollars (£1,500)." It explains that it "took this statement [regarding the dismissal of the Health Commissioner] from a responsible medical journal of New York." The question is not one of vital importance, for misinformation regarding American medical matters is not uncommon in our British contemporaries, but we should really like to know what "responsible medical journal of New York" was the authority for this statement. It certainly was not the MEDICAL RECORD, and we do not believe it was the *New York Medical Journal*, and so far as we know these are the only responsible medical journals of New York—at least weekly journals—to which presumably our British contemporary would look for the medical news of this city.

Christian Science in the Jury Box.—An individual, formerly more conspicuous than now among the New York followers of the Eddyotic creed, has been fined $100 for ignoring a summons to serve as a juror during the December term. In extenuation of his conduct the apostle of the immaterial alleged that as a "healer" he enjoyed the physician's immunity in regard to this duty of the citizen. The humor of the situation is presented by an editorial writer of the New York *Times*, who points out that the mental capacity of a person holding such beliefs is incompatible with even the modicum of common sense demanded of the occupants of the jury box. He further says that as a juror, a "Christian Scientist," being a professional contemner of all evidence and all the laws of evidence, and having a carefully trained blindness to every fact that does not come in the shape of a fee, would certainly be a spectacle just a little too ridiculous to be amusing. The real offender in this curious case is the court official who allowed the healer's name to remain among those of potential jurors for a single moment after his mental peculiarities were discovered.

Two More Quacks Arrested.—The County Medical Society is prosecuting two chevaliers of industry who have furnished a striking demonstration of the fact that the gullible in matters relating to the cure of disease are not found among the hoi polloi alone. Among the purchasers of the "magic boots" sold by this precious pair, and alleged to be curative for nearly all bodily ailments, are said to be persons of considerable prominence in social and financial circles. That this wonderful footwear was not intended for plebeian extremities is evident from the price, which, it is stated, frequently was more than $1,000 a pair.

Conviction of a Mental Healer.—After a trial lasting twelve days a notorious self-styled mental healer, who conducted a flourishing "Mental Science Institute" at Sea Breeze, Fla., was found guilty in a United States Court at Jacksonville, on February 3, and sentenced to pay a fine of $500 and serve thirty days in jail. She was charged with using the mails for fraudulent purposes, as

she treated patients all over the country by what she termed "absent treatment." The case was appealed and will now go to the United States Circuit Court of Appeals at New Orleans. This was the second trial of the healer. In the first trial two years ago she was convicted and sentenced to one year and one day in the Federal prison at Nashville, Tenn. This verdict was reversed on appeal.

Report of Committee on Nomenclature and Classification of Causes of Death.—In order to forestall the criticisms and incredulity with which the vital statistics of Chicago have been met for several years past, the Commissioner of Health, Dr. Charles J. Whalen, suggested that the Chicago Medical Society appoint a committee of experts in the nomenclature and classification of causes of death and the registration of vital statistics to make a study of the methods and work of the Health Department in these subjects, and to be empowered to report any defects discovered and suggest practicable remedies therefor. The suggestion was promptly acted upon by the society, and the following named members were appointed as the committee: Professors A. C. Cotton, Rush Medical College; N. S. Davis, Northwestern University Medical School; Adolph Gehrmann, College of Physicians and Surgeons; Ludwig Hektoen, Director Memorial Institute for Infectious Diseases; Geo. W. Webster, President Illinois State Board of Health; Weller Van Hook, Northwestern University Medical School, and Dr. J. Allen Patton. The committee submitted its report to the Council of the Chicago Medical Society January 9, 1906, by which body it was accepted and its recommendations concurred in. In substance the report of the committee was to the effect that the Health Department was obtaining accurate records of death and that its statistics might be relied on.

Medical Examiners of the Finance Department.—Dr. P. J. Murray of Brooklyn has been appointed medical examiner to the finance department of New York, *vice* Dr. A. L. Wolbarst, an appointee of former Comptroller Grout, resigned. The salary is $2,500 per annum.

Dr. Thos. R. Maxfield of Brooklyn has been appointed Acting Assistant Sanitary Superintendent of the Health Board in Brooklyn to succeed Dr. T. L. Fogarty.

Health Department to License Dogs.—A bill has been introduced at Albany to take from the Society for the Prevention of Cruelty to Animals of New York City the authority to license dogs and vest the same in the Department of Health.

Tuberculosis Exhibitions.—A tuberculosis exhibition, at which several popular lectures are being delivered, is being held at the Union Settlement, 235 East One Hundred and Fourth Street, from January 30 to February 13. The exhibition is under the auspices of the Charity Organization Society. In connection with the tuberculosis exhibition which was recently held in Boston, it is announced that the most essential exhibits will be shown in various cities and towns of the State.

The Osteopathy Bill.—Senator Hinman has introduced into the New York Legislature a bill to regulate the practice of osteopathy. The bill gives a definition of osteopathy, and provides for an independent Board of Osteopathic Examiners to be appointed by the Board of Regents on or before January 1, 1907, and serve for three years. The board is to be under the direction of the State Board of Regents, the same as the Medical Examining Board.

Dr. J. Edward Stohlman, superintendent of the German Hospital, in this city, has been appointed warden of the Jersey City Hospital, having been chosen from fifty-nine candidates for the position.

Queens County Jail.—The Queens County Grand Jury has handed up a presentment severely condemning the provision made for the insane in the county jail which it says could hardly have been worse during the middle ages.

Roosevelt Hospital.—Dr. George L. Peabody has resigned from the Roosevelt Hospital attending staff, and Dr. Frank H. Jackson has been appointed physician to the hospital to succeed him. Dr. Robert Coleman Kemp has been appointed Junior Physician to the hospital.

Ambulance Wrecked.—A Gouverneur Hospital ambulance was smashed and the horse injured in a runaway accident at Avenue D and Eighth Street on February 3. Both the driver and the surgeon escaped injury by jumping before the frightened animal collided with an express wagon and was seriously hurt.

Scarlet Fever Closes Schools.—Owing to the occurrence of two cases of scarlatina among their pupils, the New Jersey State Normal and Model Schools in Trenton have been closed.

Fifteenth International Medical Congress.—Contributions are called for to the Medico-Legal Sections of this Congress, embracing Forensic Medicine, Military, Naval, and Railway Surgery, and Hygiene and Epidemiology. All American contributors are requested to send to the president of the Medico-Legal Society the titles of such papers as they will contribute. They may be written in English, French, German, or Spanish. The preliminary program of the congress has been issued and contains plans of the building of the Lisbon Medical School where the section meetings will be held, and other details in regard to the various committees, heads of sections, etc. Information regarding the congress may be obtained from the general secretary, Professor Miguel Bombarda, Nova Escola Medica, Lisbon, Portugal.

Rockefeller Institute Fire.—Damage amounting to about $500 was done by a fire in the janitor's quarters of the Rockefeller Institute for Medical Research at 127 East Fiftieth Street, on February 2. The blaze lasted for about twenty minutes.

Bronx Medical Society.—At the next regular meeting to be held at Bronx Masonic Temple, One Hundred and Seventy-seventh Street and Washington Avenue, on Wednesday evening, February 14, 1906, Dr. Charles E. Nammack will read a paper on "The Practical Management of Typhoid Fever." General discussion by members of the society will follow the reading.

Removal of Dr. Bowditch.—In the annual report of the Massachusetts State Board of Charities, made public on January 29, the trustees of the State Sanatorium at Rutland are criticised for their action in dismissing Dr. Vincent Y. Bowditch as visiting physician at the sanatorium. The report refers to the incident as "an injudicious and regrettable step."

Hospital Commission for New York.—Mayor McClellan has appointed a commission of fifteen well-known men to act with the Commissioner of Charities, the Commissioner of Health, the Tenement House Commissioner, and the President of the Board of Trustees of Bellevue and Allied Hospitals as a committee to devise a plan of organization of the public hospital system. One of the matters to be investigated is the possibility of devising a single system of control of the various institutions

now under the management of the trustees of Bellevue and Allied Hospitals, the Department of Public Charities, and the Department of Health. In his letter to the commissioners the Mayor outlines a very broad program of study and says that he expects the commission to consider the entire hospital situation of the city of New York, to make a complete investigation of the whole subject, and after considering it in all its bearings to present a report upon which, if necessary, legislation may be obtained which will give the city a better system than that under which it is now compelled to work.

The Harvey Society Lectures.—Prof. T. H. Morgan will deliver the ninth of the Harvey Society lectures on February 17, at 8.30 o'clock in the hall of the New York Academy of Medicine. The subject will be "The Extent and Limitations of the Power to Regenerate in Man and Other Vertebrates."

The Late Dr. Ezra H. Wilson.—The Council and College Faculty of the Long Island College Hospital, having heard with profound grief of the death of Ezra H. Wilson, M.D., have ordered the following expression of the deep sense of the loss sustained by themselves personally, the Long Island College Hospital, and the Profession of Medicine, to be placed on the minutes of the board:

Ezra H. Wilson, M.D., having distinguished himself in his preliminary studies of medicine, devoted his life to the study of pathology and bacteriology. His work along these lines, as original investigator and instructor of the youth, has given his name a high place among the honored and distinguished men of the Profession of Medicine. For many years as a director of the Hoagland Laboratory, a member of the Council of the Long Island College Hospital, a member of the Health Board of this city, he exercised great influence for good. We feel that his untimely death has deprived us of a valued friend and worker, and the city in which he dwelt and the Profession of Medicine, of one of those modest, earnest, able students whose work is beyond price.

Elias H. Bartley, M.D., Joseph H. Raymond, M.D., Henry A. Fairbairn, M.D., *Committee.*

Obituary Notes.—Dr. Edward S. Dalrymple, a well-known physician of Sussex County, N. J., was found dead in bed at his home in Branchville Borough on February 3, at the age of forty-three years.

Dr. Daniel M. MacMartin, a native of Amsterdam, N. Y., died on February 2, of heart disease, at Spokane, Wash., at the age of fifty-two years. He was a graduate of the College of Physicians and Surgeons of New York, and had been located in Spokane for five years.

Dr. Asa Johnson of Minneapolis, Minn., died on January 27, at the age of eighty-one years. Dr. Johnson was born at Bridgewater, N. Y., but began his professional life at Beloit, Wis. He went to Minneapolis, then Saint Anthony Falls, in 1853, and since that time had been prominently connected with the public affairs of that city. In 1873 he became the founder and first president of the Minnesota Academy of Science. For the past fifteen years Dr. Johnson had retired from active practice.

Dr. J. R. Crofton of New London, Conn., died on January 29, at the age of thirty-nine years. He was graduated from the College of Physicians and Surgeons of New York in 1888, and served on the staff of the City Hospital and also in the Chambers Street Hospital.

Dr. Bertold Pirosh of Chicago, died on January 25, at the age of fifty-six years. He was born in Kovna, Russia, and was graduated from the University of Konigsberg in 1876, and from the Imperial University, St. Petersburg, in 1878. He went to Chicago fourteen years ago and was interested in several Hebrew dispensaries and hospitals.

Dr. John W. Long of Bryan, O., died on January 23, at St. Joseph's Hospital in Chicago, after an operation for an affection of the throat, at the age of seventy-one years. He was graduated from Bellevue Hospital Medical College in 1864, and served for a time as acting surgeon at Fort Ruby, Nev.

Dr. Alfred S. Patrick of Charleston, W. Va., died on January 23, at the age of seventy-four years. He was graduated from the Medical College of Ohio in 1853 and continued in practice until the beginning of his last illness, four weeks before his death.

Dr. John Slade Ely, Professor of the Theory and Practice of Medicine at Yale University, died on February 7 from injuries received in being thrown from his horse which was startled by an automobile. He was born in this city in 1860 and was graduated from the Medical Department of Columbia University in 1886. He studied in Europe for some time, returning to become assistant in pathology in the College of Physicians and Surgeons. He was pathologist to the first medical division for Bellevue Hospital from 1889 to 1897. In 1897 he left New York to accept the chair of Theory and Practice at Yale.

Obituary.

GEORGE RYERSON FOWLER, M.D.,

BROOKLYN, N. Y.

Dr. George R. Fowler died in Albany on Tuesday of this week, following an operation for appendicitis. He was taken ill on the train while on the way to Albany two weeks ago to attend a meeting of the State Board of Medical Examiners, and also to be present at the meeting of the Medical Society of the State of New York. Soon after his arrival symptoms of appendicitis developed, and the patient was removed to the hospital for operation. This was apparently successful, but at the end of four days intestinal paralysis developed and death followed.

Dr. Fowler was born in this city on Christmas Day, 1848, and was graduated from the Bellevue Hospital Medical College in 1871. During the Spanish War, in 1898, he served as surgeon of the Third Division of the Seventh Army Corps with Gen. Fitzhugh Lee. Later he acted as consulting surgeon and chief of the operating staff of the Seventh Army Corps, accompanying General Lee to Havana. He organized a system of hospitals for the use of disabled soldiers. He was surgeon to the Methodist Episcopal Hospital, surgeon-in-chief of the Brooklyn Hospital, senior surgeon to the German Hospital, and consulting surgeon to St. Mary's Hospital, the Relief Hospital, and the Norwegian Hospital. He was examiner in surgery of the New York State Board of Medical Examiners.

Dr. Fowler was strangely enough known as a special student of abdominal surgery, and of appendicitis in particular, and was the writer of an authoritative treatise on the subject, first published in 1894, and in a revised edition in 1900. He was also the author of numerous journal articles on surgical topics, and enjoyed the reputation of a skilful and successful operator.

Correspondence.

THE MEDICAL DISCOVERY OF OLIVER WENDELL HOLMES.

A LESSON IN MEDICAL HISTORY.

To the Editor of the Medical Record:

Sir:—The Medical Record of November 25, 1905, contains an editorial on the above subject which calls attention to the deplorable fact that "most of us have forgotten, if we ever knew, that he had claims to the gratitude of the world as a life saver and a medical discoverer." The Editor appropriately comments, "we hope that this epoch-making essay will be published in a form more accessible to the American reader."

This incident is a sad illustration of the neglect of Medical History in the curriculum of our colleges. Every child is taught the important events and discoveries of American soldiers and statesmen and his patriotism is nurtured by the recital of deeds of heroism and devotion to duty. Would not the neophyte in medicine be equally stimulated to research and to patriotic pride in the scientific achievement of his country by the knowledge of the fact that a discovery for which a monument has been erected to a Hungarian physician was antedated by an American physician five years or more?

In an address delivered before the Section on History of the Congress of German Naturalists and Physicians at Carlsbad, September 22, 1902, on "Some American Contributions to the History of Modern Therapy" (published in *Janos*, November and December, 1902, and in the *Therapeutic Gazette*, February, 1903), I dwelt with pride on this notable discovery of our own Holmes and I was astonished that in that assemblage of professors and instructors on Medical History in the German and Austrian Universities not a single voice was raised in defense of the claim of Semmelweiss, of whom I said: "Far be it from me to take aught from the man who introduced the idea successfully in Europe. To the unfortunate Semmelweiss is given the credit of being the pioneer in urging the importance of prophylaxis in this terrible scourge. When it is remembered that his mind was wrecked by the criticisms he encountered, even the most truth-loving historian must pause ere he would snatch one leaf from the laurel-crowned brow of this self-sacrificing man. Nevertheless historical justice demands that the claims of an American physician be recognized, whose views antedate those of Semmelweiss by five years, as can be established by irrefutable evidence." The latter was clearly set forth in my essay without being called in question *until after* adjournment. Then I was approached by two gentlemen, one an instructor in History of Medicine in Vienna, the other in Budapest, who asked me if I were sure of my dates and if my sources of information were reliable. On their request I submitted the manuscript to them for careful perusal. Its return was accompanied only by formal thanks. In the November, 1902, number of the historical Amsterdam journal *Janos*, my claims for Holmes were disputed by Privat Docent von Györy, of Budapest, in an essay which "does credit to the polemic ability and patriotism of the author," but only established the fact that I was in error in assuming that Semmelweiss had himself published his views in 1848 and that he really did not do so until 1861 (Die Aetiologie, der Begriff und die Prophylaxis des Kindbettfiebers). Thus was added and established by the defender of Semmelweiss an historical fact that Holmes really antedated Semmelweiss *eighteen* years, in the publication of his valuable discovery. Another historical fact was inadvertently brought out by von Györy, who stated that "His (Holmes') prophylactic measures were the same as those of the English." Semmelweiss knew them quite well, it seems, for he wrote (loc. cit., p. 146), "The English never visit a healthy pregnant or parturient woman without previously washing their hands with chloride of lime," etc. The latter practice, it may give some historical interest to this communication to state, was first used in our country in 1835 by a friend of Holmes, whose name he suppresses, but whom he quotes as having lost five cases of childbed fever and "not having encountered a single case of this terrible disease since he had adopted the practice of washing his hands in chloride of lime solution before introducing his finger into the vagina." We may therefore justly add to our claim for priority the discovery of *manual asepsis* in midwifery by an American in 1835. Owing to the meager literary interchange of thought, this fact, Holmes' great discovery, was not noticed by even the most progressive men of that time. The history of the controversy and defense of Holmes against the criticisms which, alas, degenerated into unseemly attacks by some leading obstetricians of his time, may also serve as a lesson of the hideousness of professional jealousy and self-interest on the one hand and of the beauty of Holmes' tolerance, of his sympathetic love of his kind, and of that truly poetic spirit which actuated him even in the chamber of sickness and death. What a lesson is conveyed in these noble words, quoted from his monograph, "Puerperal Fever as a Private Pestilence," published by Tickner and Fields in 1855? "The subject has the same profound interest for me at the present moment as when I was first collecting the terrible evidence out of which it seems to me the commonest exercise of reason could not help shaping the truth it involves. I have abundant evidence that it has made many practitioners more cautious in their relations with puerperal females. For my own part I had rather rescue one mother from being poisoned by her attendant than claim to have saved forty out of fifty patients to whom I have carried the disease. . . . I take no offense and attempt no retort. No man can make a quarrel with me over a mother with a new born baby at her breast! There is no epithet in the vocabulary of slight or sarcasm that can reach my personal sensibilities in such controversy. I appeal from the disparaging language of the professor in Philadelphia to the recorded opinions of those whom I do not know, and who do not know me, nor care for me, except for the truths that I may have uttered, to Copeland, who has spoken of my essay in phrases to which the pamphlets of American scribblers are seldom used from European authorities; to Ramsbotham whose compendious eulogy is all that self-love could ask; to the fifth annual report of the Registrar General of England, in which an abstract of my essay figures largely, and not without favorable comment. I will take it for granted that so far they have counterpoised the depreciating language of my fellow countrymen and teachers. The teachings of the professors of the two great schools in Philadelphia are sure to be listened to not only by their students, but by the profession at large. I am too much in earnest either for humility or vanity, but I do entreat those who hold the keys of life and death to listen to me also for this once. I ask no personal favor, but I beg to be heard in behalf of the women whose lives are at stake, until some stronger voice shall plead for them. If the doctrine I have taught is a mournful truth, if to disbelieve it and practise on this disbelief, and to teach others to disbelieve and practise, is to carry desolation into confiding families, let it be proclaimed as plainly what is to be thought of the teachings of those who sneer at the alleged dangers and scout the very idea of precaution. . . . The pestilence carrier of the lying-in-chamber must look to God for pardon, for man will not forgive him."

The dignified and solemn language of Oliver Wendell Holmes stands in painful contrast with that of his ironical but influential critics.

Another lesson of history which may be learned from this episode is the sad fact that while Holmes, the discoverer of a positive life-saving idea and practice was ridiculed in his own country by the highest authorities, among them the man who taught him midwifery and who should have been proud of the achievement of his disciple, in Europe Semmelweiss was not only ridiculed but persecuted for the same discovery by the most eminent obstetricians, among them his own teacher.

History often repeats itself. Was not Paracelsus von Hohenheim ridiculed by his contemporaries and by them handed down to posterity as a quack and pretender? And he was a man of whom the noted historian Ranke has written, "In him lived a spirit ingenious, profound, and endowed with rare knowledge." While his vanity and habits made him many enemies and his alchemistic doctrines betray only the spirit of ignorance, which was the prevailing characteristic of his time, his writings display true medical intuition in that he foreshadowed in that period of darkness and therapeutic spoliation the very truths which govern us of this advanced time. He wrote: "When disease attacks the body, all the healthy organs must combat it, for disease tends to kill them all." That which Hippocrates termed "vis medicatrix naturæ," Paracelsus termed "the inner alchemist." He proclaimed boldly what the doctor of this time rarely ventures to assert: "Nature is te physician, not you. Since I saw that the doctrines of the ancients have accomplished nothing but the making of corpses, death and deformity and decay, I was compelled to pursue truth by another way." This was a scathing arraignment of his colleagues which they naturally resented and thus the truths he proclaimed were disregarded. Whatever the failings of this man as an individual, history accords him a realization of the therapeutic aims which the physician of the present time accepts without cavil.

Other historical instances of this unfortunate tendency are seen in the treatment received by Brissot, Harvey, Audin-Rivière, and others. Brissot was a French physician of great learning and logical acumen, who insisted that "inflammation does not always demand venesection, because the power of nature, which always aids the diseased organism, may produce salutary congestion." He opposed general bleeding so earnestly that he was driven from

Paris. He died in Portugal a martyr to his love of truth, amid the maledictions of his confrères. When Broussais and his brilliant pupil Bouillaud sought to remove most diseases by bloodletting *coup sur coup*, a courageous dissenter arose in Audin-Rivière, who was a professor of Hygiene in the Lycée de Paris. A follower of Hippocrates, he scourged with the lash of brilliant rhetoric sustained by logical statistics and observations at the bedside, the spoliative practice of Broussais which had become general and literally "out-Heroded Herod." He related a mild epidemic of smallpox in 1824 in which 1,136 persons died, nine-tenths of whom had been subjected to repeated bleedings. He stated that Dr. Frappart had ordered 1,800 leaches for one patient. He was haled before the courts which mulcted him in the sum of 500 francs damages and prohibited his book. The discoverer of the greatest truth in medicine—the circulation of the blood—the justly renowned Harvey, was persecuted by reason of his teachings and lost his practice in London; his work was refused censorship in England and was printed in Frankfurt in 1628, after having been prohibited in Paris.

The lessons of humility and tolerance are constantly repeated in the history of medicine as in the history of the world. The former should be taught, as is the latter, at least in concise and assimilable form.

Simon Baruch, M.D.

New York.

THE FEE QUESTION.

To the Editor of the Medical Record:

Sir:—I read with much interest and some sorrow the article on the fee question signed by Dr. Robert T. Morris, in your issue of January 6, 1906. I did not like to see published such a statement as this which appears in the letter from Dr. G., published by your correspondent, and of which he approves: "The revenue of the medical profession has not increased at all in proportion to the revenue of the lawyer, the artist, or the artisan." The physician's fee should not be measured by that of the lawyer, nor, in my opinion, should it be measured by that of the artist or artisan. Great corporation lawyers have enormous fees, and connected with these there is not infrequently much that is wrong from many points of view. Lawyers are, no doubt, personally as kind and helpful as members of other professions, but their profession as such never was, and in the nature of things, never can be, the center of anything like the large and noble charity work that distinguishes the profession of medicine. The medical man has an ethical relation to the suffering of this world that no lawyer, as a lawyer, can ever sustain. The doctor is the trusted friend and confidant who enters unchallenged the sacred inclosure of domestic life. He takes rank not with the lawyer, but with the clergyman, and it will be a sorry day for the medical profession and for humanity when physicians come to view their financial relations with a sick and dying world through purely legal eyes. I was educated to both professions—that of medicine (Coll. Phys. & Surg., New York, 1870), and that of theology (Theol. Sem., Reformed Church in America, New Brunswick, N. J.), and I think I understand something of the difficulties of both the practitioner and the preacher; and I understand, as well, how close is the tie that unites, or should unite, them both in one fellowship of compassion and self-sacrifice. I am acquainted with many good lawyers, some of them are my personal friends, and many have been in past years my trusted parishioners, but as a profession law never called for the heroism and unselfish living that are part of the life of every true physician. I do not wish to be understood as in anywise criticising the fee named by your correspondent for the work which he described. For anything I know to the contrary, it was just and reasonable. But I do protest against introducing the advance in lawyers' fees as in any way related to the amount of compensation a physician may expect. A lawyer may work from purely mercenary motives and be a very good lawyer, but a physician moved by such motives alone could not be either a good man or a good physician.

Frederic Rowland Marvin, M.D.

Albany, N. Y.

THE FEE QUESTION.

To The Editor of The Medical Record:

Sir:—My attention has been directed to Dr. Robert T. Morris's correspondence, published in your issue for January 6, with a recalcitrant lady of his clientele, upon the ever-sensitive subject of our fees; and using the particular instance in point as a text, he preaches an admirably good-tempered little sermon.

It seems to me that the interest of the profession in Dr. Morris's correspondence gives a peculiar appositeness just now in the publication of the accompanying essay—which for lack of a better term we may entitle "The Business End of It," or perhaps "Fees and Fee Bills."

Written some little while ago, a time of especial fitness has been awaited for giving it forth. Let me hope that this is the appointed hour.

It has occurred to me that, as being almost the only topic of vital interest to a physician commonly ignored in our medical journals, this one may be worthy of a few minutes' thought. Perhaps we might call it "The Doctor's Obligation to His Family." First of all, we are medical men. But in the second place we are necessarily business men, too, and as a rule with families to support, to educate, and later to start in life. And the very practical questions when to present our bills for professional work, and upon what principles of equity to fix the amounts to be charged, deserve our attention.

There are still gentlemen who feel that these matters are unworthy the noblest of professions; that the "honorarium" (guineas delicately enclosed in an envelope and placed upon the table without comment on either side) and also the legal disabilities which, in England at least, still handicap the physician who endeavors to compel collections against dishonest patients, still constitute the right and proper condition of things; and that it is degrading to us to enforce our rights. But an increasing majority differ from this old-world view; feeling that to demand in all frankness what we have earned is no more unworthy of our dignity than it is derogatory to the dignity of the legal profession. The cases seem to me "on all fours," as the lawyers say. Even to-day the doctor's bill is among many families habitually considered last of all; nor is this surprising. One is reminded of the deacon of accumulative instincts who, upon being reproached with his systematic neglect of the contribution-box, explained that the Lord did not press him so hard as did his other creditors! The moral is not hard to draw.

As a very young practitioner I sent my bills four times a year, upon the first day respectively of March, June, September, December. This was a distinct improvement upon the method of my grandfather, who, like most of his generation, presented bills only when he was pressingly in need of money. And as to two of these four equidistant dates, the choice proved of practical value. December 1 means that the doctor's bill will stand a chance to receive prompt attention, whereas a month later it would be lost amid those arriving thick as snowflakes upon January 1. Again, June 1 is a desirable date, for then one may chance to receive his money, whereas a month later it is in hopeless competition with summer hotel bills, *et id genus omne*.

But after some years of experience it was decided to render accounts upon strict business principles, the first of each and every month (except during the continuance of a case), and to have engraved upon the billheads, "Bills presented monthly"—by way of indicating that nothing invidious is to be inferred by the patient in any instance.

In no case has this plan induced death from heart-failure at the shock of finding the physician to be also a man of business. On the contrary, I am satisfied, after many years of trial, that my patients—the honest ones, who are a great majority—prefer this plan. Should an error in bookkeeping arise, it enables them to go back in memory over the brief interval since the preceding bill, and correct it. Moreover, it is unquestionably easier for them to pay, and for the doctor to collect, ten dollars twelve times a year, than a hundred and twenty dollars once a year—or even than thirty dollars four times a year. And further, we should remember that gratitude, like alcohol, though a heart tonic, is volatile; and we should use it while it lasts.

Most doctors are their own bookkeepers. As a class, they do not earn their salary as such, and should discharge themselves. The tired, overworked practitioner will always postpone until that more convenient time, which so seldom comes, this particularly unpleasant duty. I believe that it will pay all, except those just beginning and hence with very small practices, to hire an accountant by the year, turning over to him the pocket day-book at the end of each month, and giving him a schedule of prices for certain work, as a general guide. There are hundreds of bookkeepers who will be glad, in return for a trifling sum earned outside of their business hours, to do this work. The bills thus prepared are to be examined in review, just before mailing, by you, in the accountant's presence. He may also be willing, for a moderate percentage, to attend to collections requiring the gentle admonition of a personal call.

This naturally brings up the further question

as to the size of our fees—which needs agitation, if ever a topic did. Even the best brains of our profession are not paid as they deserve to be, and as—for example—eminent lawyers are. Take the instance of Senator Conklin. Being an honest man, he left the United States Senate in debt. But within the few years elapsing between then and his death, in consequence of the great blizzard, he had through legal fees cleared himself, and left a fortune of more than $100,000. Such a thing would be an utter impossibility with us. And yet, in consideration of the good accomplished by our ablest men, and of the awful, the crushing responsibility of life or death sometimes upon our shoulders, no fee is high enough. It is a ludicrous mental and moral obliquity to hold, as I have heard urged, that such work is beyond all price, and that this is why even their wealthy patients cannot attempt to compensate them for it! I regard our greatest physicians as invariably underpaid. If, by some simple suggestion—but born of genius wedded to experience—a brain is saved from insanity by the neurologist, a mind that otherwise must have entered oblivion, then a fee of a hundred thousand dollars, in the case of a millionaire, would be small indeed for that work. The specialist would, in that case, still be underpaid; he would still deserve our commiseration; but not so much so as usual!

In most such instances that brain specialist is indeed lucky if he adds a twenty-dollar fee to his slender bank account. And were he to charge a tithe—a mere vulgar fraction—of the first-named sum, that patient, the man of wealth, would use his restored mentality in devising lurid invectives to fit this peculiarly atrocious case of robbery! On the other hand, an able consulting *lawyer*, who should win some great transcontinental railway suit for this same millionaire by raising some shrewd legal point, would name, with calmness, a fee of five or even six figures, and it would be paid as a matter of course—and without unseemly wrath. Who shall say that this picture is overdrawn?

As to the rank and file of the profession, we exhibit our lack of business ability and invite the contempt of the ungodly in nothing so much as in our failure to combine for mutual protection against miserably insufficient prices for our work, as also in our lack of cordial mutual support. I have small patience when I hear, as I have repeatedly done, the argument used that we should charge all people alike, without regard to their financial condition; that if we charge Mr. Smith $50 for setting a broken bone, we have no right to charge Mr. Jones $500 for the same thing. Still less do I rejoice and give thanks when the speaker is a doctor, who maintains that the brother-physician, in the instance of a given wealthy patient, whom he has cured, has "overcharged"!

Let me illustrate by a parable. The Emperor, William I, of Germany, was fond, like Haroun al Raschid, of the "Arabian Nights," of mingling among his people unknown—or thinking himself so. Once upon a time, while wandering at night through a crowded market place he priced the eggs offered by a certain old woman. Startled at the sum she named per dozen, he exclaimed, "Can it be that eggs are indeed so high as a mark a piece?" To whom returned the *handelsfrau*, "Nay, your Majesty, eggs are plentiful enough; it is *Kings* who are scarce!"

Now, all can see the gross injustice herein attempted upon an inoffensive and harmless monarch. But the fable, as I maintain, presents a parallel with our case. We are not selling our brains over a counter to all comers indiscriminately at so much per think or per dozen thinks. The Smith-Jones argument above mentioned comes with ill grace when directed against a profession which serves the poor without money and without price, to such an extent that a huge proportion—perhaps not less than one-fourth of the population of the great city of New York—receive their medical attendance free. Those who can pay, should therefore, it would seem, do so somewhat in proportion to the extent of their means; at least for operative and for consultation work involving unusual experience and ability.

This principle of a graded scale of charges is certainly the one approved of by the legal profession; the difference being that we have less of the courage of our convictions than have they, in carrying it out. For example, most of us would not assess a poor clerk for expert work as much as we would charge a millionaire for that same service. This fact being admitted, the principle just asserted is also admitted. And logically, if we charge that clerk (let us say) one dollar, as a bill for our services, we should charge the man of money many thousands for the same thing, in order to maintain the same proportion. This is not always feasible; but let none of us who admit that we do not have an identical fee-bill for wealth and poverty alike, assail our more logical and consistent brothers who charge somewhat in real proportion to means as well as to the good accomplished. And let none of us do that shabby thing so common in our profession of intimating that a given fee is too high, and that we, if called, would have charged less!

One further point, often neglected: the family doctor can better judge than the man whom he calls in consultation, as to the patient's fortune, and therefore as to what would constitute a fair fee in a given case. It is a wise custom for the specialist to submit his proposed charge first to you who called him in, and to be guided by your decision in this matter. Should the operator offend the patient by the size of his bill, the doctor who has recommended him may suffer a vicarious punishment from the subject, subsequently. Therefore, the arrangement just named seems but courteous to the family attendant.

It has long seemed to me that much good would result if in all our medical schools one of the professors would address the graduating class upon the eve of their leaving their *alma mater*, giving a little lecture full of kindly advice upon just such practical topics as these now under discussion. The average income of our profession is undoubtedly pitifully small. If this were better known its ranks would not be so crowded. The more reason why we should help these young men, about to encounter much competition—at least in town—to avoid certain financial blunders which most of us have committed, because uncounseled. It might even be well to point out the unwisdom of speculation—as with time the question shall arise how best to invest their hard-earned dollars. The young doctor can in most cases take no wiser step than to endeavor to buy the house in which he lives, making steady if small payments upon the mortgage. Real estate cannot take unto itself wings.

Advice coming from the lips of a professor to whom these lads look up with a real reverence—as is often the case—would be apt to be followed implicitly; for "just as the twig is bent the tree's inclined." It would earn their subsequent and lasting gratitude; and by inducing sensible business methods, and even concerted legal action in certain localities, for mutual protection in financial matters, would compel a respect in others for our calling as being one eminently worthy the best treatment, rather than as now often the worst, at the hands of a business community.

ROBERT H. M. DAWBARN, M.D.

105 WEST SEVENTY-FOURTH STREET, NEW YORK.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE GENERAL ELECTION AND MEDICAL CANDIDATES—ANNUAL MEETING OF THE GYNECOLOGICAL SOCIETY—COLOTOMY—TORSION OF THE OMENTUM—BIRTH RATES—PUERPERAL FEVER—NURSES AND REGISTRATION—OBITUARIES.

LONDON, January 19, 1906.

ALL the week we have been engaged in the excitement of a general election. You will have learned from day to day many of the surprises that have occurred, which have brought about a complete change in the position of parties. Although the usual prophecies of success were made by partisans, it is certain that both victors and vanquished are amazed at the decisive result. No one seriously pretends to any other conviction. The position of the profession in the new House of Commons is at present uncertain, but we do not expect very much. Hopes are expressed that from six to ten doctors will obtain seats. Almost the lower figure has already been reached. There has been some heart-searching among political doctors as to whether they should vote for one of their profession, irrespective of his party views. Yet, while other classes are working to obtain representatives, it seems but natural that we should follow suit—especially as questions of sanitation and other matters on which skilled advice is urgent, are sure to arise.

The British Medical Association has submitted to candidates a series of questions, and thereby has elicited a number of promises to support the measures it has brought or will bring forward. Perhaps such a proceeding may prove important as showing that the general apathy of the profession must not be too implicitly trusted by members of the new Parliament, but it is hardly desirable that the association should be thought to be quite representative of the medical world. It has too often done what we cannot approve. Moreover, at first the new government seems likely to be so strong that it will be as indifferent as its predecessors to medical opinion.

The annual meeting of the British Gynecological Society was held on the 11th inst. The treasurer's report and balance sheet showed the prosperity of the society continues, and a hearty vote of thanks was accorded him. A report was also presented by the editor of the *Journal and Transactions*, which elicited equally cordial thanks. Mr. Jessett,

in proposing this vote, said that under Dr. Macan's editorship the *Transactions* had become a classical work, not only on account of the original papers and record of the society's work, but also through the abstracts and reviews of gynecology in America and on the Continent, and the contributions of foreign authorities. Votes of thanks were also accorded to the auditors and honorary secretaries, and the election of officers for the year was taken. Mr. Bowerman Jessett, who occupied the chair in 1893, was elected president for the year.

At the Clinical Society on Friday, Mr. Lawrie McGavin read a paper on colotomy, in which he pointed out the disadvantages of both the lumbar and iliac operations, and advocated the plan of opening the transverse colon as the routine operation. This he considered gave a firmer support for the belt and plug, less liability to prolapse, rendered the operation more simple, owing to the mobility of this part of the bowel and the increased ease with which a sphincter can be obtained. He also said the position of the new anus was better for the more comfortable evacuation of the bowel, and the transverse colon could more easily be reconstituted should occasion arise. Out of four cases of iliac colotomy, difficulty of control and prolapse had been complained of in three, in spite of belt and pad. Notes of three cases by the transverse operation were read. In all the control was good, prolapse absent, and the general comfort greater than average cases by the iliac plan. He thought further improvement might be effected by dividing the bowel, closing the distal end and drawing the proximal through a broad band of fibers from the rectus muscle and suturing it.

The president, Mr. Clutton, said that nowadays he never met with prolapse after inguinal colotomy, and did not find any apparatus necessary. As to utilizing the rectus, that was the rule in iliac operations.

Mr. Harrison Cripps said he had performed above six hundred inguinal, but only about a dozen transverse colotomies. He agreed that the lumbar method was obsolete. The after difficulties of colotomy were (1) prolapse—a rare occurrence at the present day, as it could be prevented by not making the wound too low, insuring no slack bowel was left above the wound, and making the opening the right size. (2) Retaining the fecal matter. The point was to obtain sufficient solidity, the contents in this respect differing between the transverse colon and the sigmoid. (3) Decomposing mucoid secretion in the distal part, which occurred in 20 or 30 per cent. of the cases. In inguinal colotomies this could be treated by syringing through, but this was impracticable in transverse colotomy, which last, he thought, should only be performed when the obstruction is too high to permit the iliac operation.

Mr. Openshaw agreed with the last speaker, and would resort to the transverse operation only when the obstruction was in the splenic flexure.

At the same meeting Messrs. Pinches and Corner reported two cases of torsion of the omentum complicating inguinal hernia—a rather rare event, as only fifty-five cases have been previously recorded. Mr. Clutton discussed the significance of strangulation and torsion. Mr. Forbes Ross did not think the diagnosis from appendicitis important, as the operation would show the condition. Mr. Spencer thought there was no a priori reason why torsion should not occur; he had met with it in femoral hernia. How was the diagnosis arrived at?

Mr. Pinches replied, by finding an inflamed hernia with extensive tenderness of the abdominal wall in a patient previously the subject of a freely-moving hernia.

No little fuss has lately been made about the decline of the birth rate. The press generally regards it as another indication of our degeneracy, but a few enthusiastic malthusians hail it with satisfaction. The subject has been discussed by the Royal Statistical Society from a different point of view. Drs. A. Newsholme and T. H. C. Stevenson contributed a paper introducing corrected birth rates, making allowance for the fact that some populations included more wives at child-bearing age than others. This corrected rate gave very different figures from the "crude" rate; *e.g.* the birth rate of Ireland in 1903 was 23.1, a little higher than that of France—21.7. But the French rate was practically unaltered by correction, whereas the Irish rate was made 36.1. This was attributed to the fact that, though both countries had about the same proportion of women aged 15 to 45, the proportion of these married was 52.5 per cent. in France and 32.5 per cent. in Ireland. A study of statistics of other countries showed the authors a decline of fertility generally to the extent of 17 per cent. in England and Wales, 18 per cent. in New Zealand, 24 in Belgium and Saxony, 25 in Victoria, and 33 in New South Wales. The actual present birth rates were also examined and led the authors to conclude that a decline is associated with a rise in the standard of comfort in a community—a determination of people to secure this comfort. They had no hope that any nation—in the absence of overwhelming moral influences—would be left behind in this race to decimate the race, and they anticipate a deterioration of the moral, if not also the physical, nature of mankind.

The foregoing paper was followed by another by Mr. G. U. Yule, who compared the fertilities of married women in different districts of London in 1871 and 1901. In the upper-class districts the fertility dropped about 20 per cent., while in the lowest it was practically unchanged. It must, however, have fallen among the working classes generally, as the fall in the upper-class districts was little more than in the country at large. The fluctuations in the birth rate, as in the marriage rate, appear to correspond with the cycle of trade and industry. The movements of the marriage rate are more irregular than those of the birth rate. The fall in the latter is associated with a fall in prices.

An object lesson comes from Manchester, where the isolation hospital admits cases of puerperal fever. According to a paper by Dr. Gordon, out of thirty-seven such cases, twenty-three had been attended by midwives and fourteen by medical men. In the midwives' cases, symptoms set in from the fourth to the eighth day, and there had been no operation. In all the microbe was the bacillus coli. In the doctors' cases, symptoms set in generally within forty-eight hours and there had been operative interference. In these the organism was a streptococcus, mixed occasionally with the bacillus coli.

The Nurses' Association has held another meeting in support of registration. The spectacle-makers, having set up as sight testers, are demanding a similar degree of recognition and protection. At this rate we shall soon have every form of quackery and imposition asking for state registration and selling diplomas.

Mr. J. H. Ceely of Aylesbury (where he was surgeon to the hospital from 1832 to 1882) died in London on the 25th inst., aged 96. He was a London Hospital man. He took L.S.A. in 1830, M.R.C.S., 1832, was elected to the fellowship, 1852, where he had obtained a high position as an operator in Buckinghamshire.

Surgeon-General Sir Joseph Ewart, Ph.D. St. And., F.R.C.P., died on Wednesday at Brighton, where he lived after retiring from the army, and took a great interest in all public matters. He was three times mayor of Brighton, consulting physician to the Alexander Hospital for Children, and held other medical appointments. He belonged to the Indian Army and served in the mutiny. He had been professor and senior physician in the Calcutta College Hospital, examiner and principal in the university, and he was also editor of *Indian Annals of Medical Science*, and author of many papers on Indian mortality, tropical diseases, snake poisoning, and other topics within his extensive experience. His first diploma was dated 1853.

Lieut.-Col. C. S. Close, R.A.M.C., retired, died on the 30th ult., aged 68. Dr. Kershaw of Leeds died on the 4th inst.

Dr. Wm. Graham, J.P., M.O.H., for Middleton, also died on the 4th, aged 51. He graduated at the Royal University of Ireland in 1883. He wrote on public health questions, was a D.P.H. of Victoria University, and a zealous sanitarian.

Dr. H. Campbell Pope died suddenly on the 2d inst. He had served as president of the West London Medico-Chirurgical Society, of which he was one of the founders. He took M.D., London, 1878; F.R.C.S., 1876.

The death is also announced of Dr. Thos. R Adams, J.P., consulting surgeon Croydon General Hospital and one of its founders.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

GARDENING AS A PLAN OF TREATMENT—A MEDICAL ELECTION—OXYGEN IN SURGICAL DISEASES—TUBERCULOSIS AS A HOME DISEASE—RENAL TUBERCULOSIS—RESECTION OF THE FIFTH NERVE.

BERLIN, January, 20, 1906.

ALTHOUGH the originator of the idea of treating various diseases by having the patient engage in garden work is perhaps rather too sanguine in his expectations, the results obtained in this way at least deserve mention. Fifty-one patients suffering from anemia, neurasthenia, chronic gastritis, constipation, chronic bronchitis, and acne were treated in twenty-six gardens. Only thirty-one patients worked regularly during an entire month, the others in some cases continued the treatment a little longer, but in most instances it was carried out for a shorter period. Seven patients out of eighteen with anemia, and eight out of thirteen with neurasthenia were greatly benefited. The gardeners' unions have objected to the plan on the score that its popularization would cause a weak type of individuals to become gardeners who would also be willing

to work for a less compensation than the regular workmen. These objections, however, have but little force, for the work is not only exacting but also has other disagreeable features, and patients would scarcely be able to work continuously as is required of regular gardeners. The conclusion is that the treatment by garden work is satisfactory and yields good results, but its efficiency depends on the nature of the patient's affection, his natural ability, and other circumstances such as the weather, the distance that must be traversed to reach the garden, etc.

Considerable interest has recently been excited by the elections for the Aerzte-Kammer. A few words will suffice to indicate the importance of this. Every province of Germany has its own chamber, the members of which, numbering forty in Berlin, are elected by all the physicians of the province. The government officially recognizes the organization by delegating a representative to attend at each session and in addition accords certain privileges to it. Every physician is legally obligated to give a part of his income to the body, which in this way accumulates a fund for the purpose of assisting needy physicians or their families. The organization is further empowered to censure or to impose a fine up to the sum of 2,000 marks on any physician whose conduct is derogatory to professional honor. At the recent election all of the medical societies seemed to be in accord in regard to the nomination of candidates, when suddenly another ticket was submitted comprising a list of physicians for the most part entirely unknown to the medical world of Berlin. On investigation it was found that this ticket was backed by a very small fraction of the medical body who in opposition to nearly all German physicians wished to restrict the treatment of lodge members to a few physicians, members of the "Verein fixierter Kassenaerzte." It appeared that this association had acted in connection with some of the large Berlin lodges in order to deprive many of the profession of a large source of income by the selection of other candidates, but although for a short time it seemed as if the second ticket was not without chances of success, at the final election the first ticket was carried by a great majority.

Wohlgemuth, in a paper entitled "Sauerstoffinjectionen bei chirurgischen Infectionskrankheiten," head before the Medical Association, describes a new treatment of septic processes. The use of oxygen in surgical diseases is old but it has never been followed by any remarkable effects. The speaker had developed the plan of injecting oxygen gas into the tissues in cases of inflammation, especially those caused by anaërobic bacteria. Furuncles, carbuncles, septic wounds, panaritia, and phlegmons, which usually required long courses of treatment were quickly cured by oxygen gas. The secretion of purulent sinuses could promptly be checked by daily treatment with oxygen, and the burning pain in infective bruises soon ceased. In panaritium and cellulitis large incisions were unnecessary if the wound were treated with oxygen through a small incision and the gas injected into the surrounding tissues. The most surprising effect was to be seen in the treatment of furuncles which were often cured in one session. One disadvantage pertained to the method, however, as the injections were rather painful. The technique was very simple; a small cylinder of 100 c.c. capacity was filled with oxygen at a pressure of one hundred atmospheres and provided with a rubber tube ending in a sharp or blunt needle. The pressure best adapted for the purpose was of such a degree that when the stream of gas was allowed to escape under water it appeared to make it boil. The needle was inserted into the tissues about the furuncles until these had been entirely encircled.

A paper of great interest regarding the principles of tuberculosis treatment was read by De la Kamp before the Society for Internal Medicine; its title was, "Tuberculosis Sanatoria in Relation to Home Life." The speaker had examined the families of tuberculous patients who had been in the large sanatorium at Grabowsee. Seven hundred and fifty families were examined and it was found that 246 wives out of 573 were suffering from tuberculosis; of the remainder whose lungs were in good condition 158 were the victims of other diseases; of 1,340 children examined 656 showed signs of tuberculosis, at least in regard to glandular involvement. The examination of 85 patients formerly treated in this sanatorium showed that 76 were in a condition to require readmission and in 5 of these the disease had progressed. There is no doubt, however, of the value of sanatorium treatment, as the disease appears to run a more benign course in such patients than in others. It is apparent that tuberculosis is a "home disease" and that one of the most important features lies in the education of the patients as conducted in the sanatoria. The best means of combating the disease is to contribute large amounts for the reform of lodging conditions among the poor. To cure the father without curing the family is only half a cure.

At a recent session of the Medical Society Israel demonstrated the wealth of the material available in his hospital. Sixty-six cases with primary renal tuberculosis were discussed by Rosenstein in a paper entitled "The Minute Anatomy of Renal Tuberculosis." The speaker distinguished three varieties, (1) the caseo-cavernous form, (2) tuberculous ulceration of the point of the papillæ, (3) diffuse tuberculosis. He did not recommend exploratory laparotomy in doubtful cases as exact diagnosis was impossible without dissecting the organ. It was possible that in the course of time it would become practicable to resect only the involved portion of a diseased kidney without extirpating the whole organ. Neuhauser reported on other cases operated on by Israel. Of 102 cases of renal tumor 68 were hypernephromas, the others sarcomas, carcinomas, and mixed tumors.

The general practitioner found much of interest in a paper by Gege read before the Berlin Surgical Society and dealing with the results of peripheral resection of the trigeminal nerve. The author reproduced the operative statistics of Fedor Krause. Out of seventy cases operated on five suffered from symptoms of hysteria, which in four cases were aggravated after the operation. Replies concerning their condition were obtained from fifty-five patients. Three and a half years after operation eleven patients remained free from attacks but all the others suffered from a recurrence after, on the average, twenty-six months; but even in these cases great improvement was noted because the attacks were of a more favorable nature and were more easily controlled by other antineuralgic remedies than had been the case before the operation.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 1, 1906

The Sanitary Importance of Clean Milk.—C. Harrington declares that ordinary market milk is almost everywhere a polluted, dirty food. It contains large numbers of bacteria, due to disease or lack of care in production, storage and handling at the farm, during transportation, and in the home. He describes the various modes of contamination from the time milking begins until the milk is on the table of the consumer. One very common infecting agent is Klein's *Bacillus enteritidis sporogenes,* which occurs in horse (not cow) manure, and is constantly being blown about in city air. Another cause of intestinal disease lies in the streptococci and other organisms contained in the pus contributed to the milk of cows suffering with garget, which is the most common of cattle diseases. Not only is bad milk injurious to young children, but it is injurious also for invalids and convalescents. In Massachusetts, dirty milk causes more typhoid fever than does polluted water. As regards the tuberculosis question, it is clear, in view of the evidence now at hand, that tuberculosis, especially of the digestive tract, can be and is transmitted by such milk, especially if the disease in the cow has become localized in the udder. It is difficult to arouse public sentiment on this question, but the remedy is simple. We should insist upon clean milk and be willing to pay for it; encourage the production of a sanitary supply, and refuse to buy excrement and pus; buy of the man whose supply costs a cent or two more per quart to produce, and let the sloven learn that cleanliness is an asset and filth a heavy load to carry.

A Report of Two Cases of Erythema Multiforme Desquamativum.—The cases are reported by P. K. Brown, who refers to Osler's collection of twenty-nine previously recorded cases. Of these two patients, one had gastro-intestinal crisis fever, joint, heart, and kidney complications; the other had intestinal disturbance, fever, slight kidney disturbance, angioneurotic edema and purpura, with mucous membrane hemorrhages. None of Osler's cases had the scarlatiniform variety of erythema, which seems usually not to be associated with as severe conditions as in these two instances. Detailed clinical histories are given of the latter. The author notes that most authorities agree that erythematous manifestations occur most often in gastrointestinal intoxications, from poisons introduced into the stomach, or from errors in metabolism. A great variety of types of erythema are reported under this heading, and the literature on the subject increases the list of substances classed under poisons all the time. Quite recently the various antitoxins have been added to the already long list. Diphtheria antitoxin was added to the list from the date of its first use. The cases with eruptions and gastrointestinal crises are, as a rule, the least serious form of the trouble, unless other complications supervene, as they are likely to in case the attacks recur. The similarity of the disease to scarlatina was well illustrated by the author's cases. The rash was hardly distinguishable from scarlatina, and desquamation took place all over the body. Cases are recorded in which recurrences are frequent, complete desquamation taking place each time, the intervals between the attacks being so short that the skin in some parts of the body was constantly in a state of exfoliation. This

condition resembles closely the exfoliate type of dermatitis, which is not infrequently the terminal condition in this peculiar disorder. What helps further to distinguish it from scarlet fever is its earlier period of desquamation, the rather striking absence of throat symptoms in a majority of cases, its recurrence, the absence of the peculiar pale ring about the mouth, and a disproportion between the fever and the intensity of eruption.

New York Medical Journal, February 3, 1906.

Tuberculosis of the Vermiform Appendix.—H. A. Haubold reports one case, that of a boy of nineteen years, without antecedent history. Initial symptoms of two days' duration, consisting of abdominal uneasiness and constipation, slightly distended abdomen, with some tenderness in the lower right segment, were relieved by free catharsis, but recurrred two days later and led to abdominal exploration. An intramuscular celiotomy evacuated a pint of milky fluid from the peritoneal sac. The omentum was adherent to the appendix at its distal end. The appendix was much thickened, with a hard exudate. No tuberculous foci were noted in the peritoneum, nor was there any fibrinous exudate or free pus. Immediate recovery from the operation was good, but the wound showed no tendency to heal. In the meantime the pathologist had reported the existence of tuberculosis of both appendix and omentum. In three weeks the wound had become reduced to the size of a large fistula, but never entirely healed. The patient gradually emaciated, with low fever, but no cough or expectoration. Examination of the lungs was negative. Death followed nine weeks after operation. No autopsy was held. At no time after the operation was there any evidence of infection from pyogenic bacteria.

Hereditary Syphilis.—An interesting series of cases is presented by R. W. Taylor, who first briefly reviews the progress of studies bearing on the etiology of syphilis in general. Concerning the *Spirochæta pallida*, he says that "the conviction is fast impressing itself on the medical mind that at last we have discovered, if not the true causal agent, at least a microorganism which is in some way concerned in the inception and course of syphilitic infection." Taylor believes that the disease can be transmitted to the third generation, and records two personal cases going to prove this view. Much light has been thrown on the question of the immunity of heredity syphilitics to subsequent acquired infection. We now recognize cases in which "syphilitic heredity" occurs, cases in which simply a dyscrasia is transmitted, which while it may greatly weaken its possessor and retard its growth, shows itself only in dystrophic changes in which several or many tissues or organs are involved in nutritional disturbances. Under favorable conditions, treatment will generally bring such patients back to a standard of health wherein they possess no immunity to acquired infection. On the other hand, severe cases occur, in which the resemblance to true acquired syphilis shows itself and which is a truly malignant condition, capable of transmitting the infection in early years to a healthy subject and running a more or less severe course, according to the activity of treatment. Such patients possess as a rule immunity to subsequent acquired infection. Rarely, owing to changes in nutrition not understood and chiefly to the efficiency of treatment, the hereditary disease seems to become extinct. The immunity is then lost, and the patient may, under favoring circumstances, contract syphilis. Naturally changes in patients of the third generation are more generally of the dystrophic rather than of the virulent form. Death without apparent cause is peculiar to the syphilitic children of the third generation. Abortions and miscarriages are rarer in the third generation, and do not constitute a pathognomic sign, as in hereditary disease of the previous generation. As a rule, syphilitic infants of the third generation do not present in the first six months of life any characteristic anomaly, and they may appear healthy during the first few years. Then, without appreciable cause, they become thin, with more or less dwarfing of their physical and mental functions. Intranasal affections very often mark the syphilis and lead to a fatal termination.

American Medicine, February 3, 1906.

The Readjustment of Education and Research in Hygiene and Sanitation.—William T. Sedgwick urges that a sharp separation be made between sanitary and hygienic work in research and education, claiming that such a separation exists already in fact, and that its recognition would promote the interests of both branches of general hygiene. He would have sanitation mean chiefly the care of the environment (streets, water, milk supplies, sewerage, etc.), and hygiene chiefly the care of persons or groups of persons (feeding, vaccination, personal hygiene, etc.). The latter would then belong largely to medical men or physiologists, the former to sanitary biologists, chemists, and engineers. He laments the small attention paid to hygiene and sanitation, alike in medical schools and in schools of engineering, and looks for a remedy partly in the better definition and separation of these subjects, and partly in the establishment of permanent, well paid positions for trained men in the public health service,—which should at the same time be made more general and less local. He pays his respects to political boards of health as follows:—Politics must also be wholly eliminated from our boards of health, both state and municipal. There is no republican method of vaccination, no democratic plan of street cleaning, and places on boards of health must not be used as rewards of political activity. The time,—if it ever existed,—has gone by when a good board of health can be made up of a political doctor, a political saloon-keeper, and a political nobody; for no well-trained and self-respecting expert in hygiene or sanitation can or will remain in the dubious and uncertain service of weak, incompetent, or shifty characters.

Some Observations on Albumoses in Urine.—Warren P. Elmer after mentioning the discoveries of Bence Jones and discussing briefly the subsequent contributions to our knowledge of albumoses in urine, takes up their clinical significance in general and mentions the following as the diseases in which albumosuria most frequently occurs. Multiple myeloma of bones, tuberculosis, especially pulmonary, croupous pneumonia in the stage of resolution, septicemia, pyemia, abscess, carcinoma, and sarcoma when undergoing rapid retrograde change. The leukemias and Hodgins disease after treatment with Röntgen rays. The various tests for albumoses are considered at some length and he recommends the following as the most practical: The reagent consists of a 50 per cent. solution of sulphosalicylic acid in distilled water. This reagent precipitates on contact all proteids found in the urine, but the albumoses redissolve on warming the urine, while albumins, globulins, etc., do not, so that when any or all of the albumin group are present with albumoses filtered the warmed urine will separate them, and the albumoses be determined by cooling the filtrate. Care must be taken to avoid prolonged boiling, for if mucins be present they may be broken down, one of the products being an albumose. A very small quantity of albumoses may be detected by dividing the urine after adding the reagent and warming one part while cooling the other and comparing the tubes before a dark surface. In conclusion he cites 34 cases of albuminuria in various diseases, with a comparison between the variations in the amount of albumoses in the urine and the leucocyte count as an index to the patient's condition and concludes that especially in destructive processes in the lungs the albumoses in the urine are a more delicate guide than is the leucocyte count.

Röntgen Rays in External Treatment.—M. B. Hutchins discusses the mode of action of the rays and the various diseases in which patients have been reported cured or benefited. He especially emphasizes that mild prolonged or short strong exposures of the skin or incomplete action of rays may produce epithelioma, and that imperfect and unskillful Röntgen-ray exposures can so complicate a case as to render the use of any treatment, or hope of cure, quite vain.

Journal of the American Medical Association, February 3, 1906.

The Arctic Climate.—F. Sohon describes and illustrates by a chart and photographs the advantages of the arctic climate for the relief of chronic affections, particularly tuberculosis. The continuous sunshine and its marked effect on animal and vegetable life in these regions during the summer months as well as its increased actinic quality, the dustless and germ-free atmosphere, and the effect of the sea air under these conditions are all noted as factors in causing the special salubrity for respiratory affections. He sums up the merits of the arctic climate for this class of cases as threefold: "First.—It holds absolutely nothing to add fuel to the existing flame. There is no dust to irritate tissues already struggling against a present mastery of the disease, no superadding of pus or other infections, no contracting of colds to invite a setback, nothing to depress vitality. Second.—It holds every incentive to an increase of bodily vigor. Each and every chance and opportunity for a cure which is here sought for and obtained only singly and indifferently is there grouped together in full intensity without the necessary presence of any disadvantageous element. Third.—As a result of this dual combination, a beginning tuberculous process may be checked in the shortest space of time, and not so much local damage will be done while waiting for the tide to turn and recovery to begin. This will lessen the chances of a new infection occurring after a cure." He believes there is a chance here for benevolent enterprise with a surety of results.

Localization of the Higher Psychic Functions.—After first sketching briefly the history of the present status of the question of cerebral localization, C. K. Mills and T. H. Weisenberg bring forward the data and reasons for the

belief that the prefrontal lobe, that is that portion of the brain anterior to the motor centers, and especially the left prefrontal lobe, is the center for the highest psychic functions. First, they find much evidence of value in support of this view in the studies of human and comparative morphology and anatomy. Brains of persons of known intellectual power show a special development of this region, and if such brains are compared with those of human beings of low individual or racial development the psycho-physiological importance of the prefrontal region becomes more apparent. Exceptionally the left lobe has not the highest development as compared with the right, and in studying the conditions a careful comparison should be made between the gyral and fissural characteristics of the prefrontal and parieto-temporo-occipital areas. Morphological studies of the brains of imbeciles support the theory of the higher psychic functions of the anterior lobes, and the embryological studies of Flechsig and the histological researches of Campbell show, among other things, the absence of projection cells and fibers in this region of the brain. Campbell speaks of it as the very last pallium to appear in the progress of phylogenesis, which is in accordance with the view here expressed as the highest and most specially endowed portions of the nervous system are the latest to appear. Gross and microscopic examinations of the brains of general paretics afford support to this view, and it is probable that a careful study in cases of dementia præcox will also afford like evidence. If the prefrontal lobe is the seat of the higher psychic action, the suggestion naturally occurs whether it can be subdivided into subareas or centers. The difficulty of answering this question is evident, but the authors suggest as a possible clue the position of certain known motor centers that are most clearly associated with psychic functions, such as those for speech and for the movements of the head and eyes, which project from the precentral convolution into the prefrontal lobe. They criticise the work of certain authors who have questioned the psychic function of the prefrontal lobes and point out their fallacies and defective methods of study. The paper concludes with the report of a case of tumor of the prefrontal lobe bearing on the subject here discussed.

Delayed Chloroform Poisoning.—H. G. Wells explains the late mortality after chloroform administration, to which attention has been called by Bevan and Favill and others on the theory that chloroform, a protoplasmic poison, when in sufficient quantity in the blood, inibits the proteolytic activities of certain of the cell enzymes, while autolysis still goes on and this, with the accumulation of toxic substances due to the impaired functions of the degenerated liver and kidney, is the cause of the symptoms of late chloroform poisoning. Just what cell elements are selectively inhibited cannot be definitely stated, but he believes that the oxidative ferments are chiefly involved. If the oxidases in the cell were destroyed or inhibited we would see just the changes observed in chloroform poisoning, and we should look for the appearance of organic acids in the urine, such as we find in these cases. The liver is probably most affected because it is the most active organ in the autolytic and oxidative processes of the body. The summary of his views is given by Wells as follows: "Chloroform poisoning, in common with a number of closely related conditions characterized by intoxication and marked changes in the liver (acute yellow atrophy, phosphorus poisoning, certain septicemias, and some cases of puerperal eclampsia) probably all depend on the effect on the liver of poisons that destroy the synthetic functions of the liver cells without destroying their autolytic ferments. Autolysis of the liver cells follows, with resulting alterations in the liver structure, and the appearance of the products of autolysis (amido acids and various other organic acids) in the blood and urine. It is probable that in chloroform and in phosphorus poisoning, at least, it is the oxidizing enzymes that are particularly involved, accounting for the marked fatty changes that are present in these conditions."

A Remedy for Cholera.—C. D. Ussher, inspired by Koch's statement that quinine in 1/1000 to 1/2500 solution destroyed the cholera germ in from ten to thirty minutes, has used the drug in the treatment of cholera, giving ten grain doses every hour till bile reappears in the stools; from forty to eighty grains have been given. While under the old treatment nearly every case was fatal, under this medication 90 per cent. of the patients recovered, including some who were almost moribund. The routine method is described as follows: Quinine sulphate, 10 grains every hour till ricewater stools ceased and bile reappeared; sweet spirits of niter, dry cupping, heat, and friction for suppression of urine; saline injections when the wrist pulse had disappeared (some of these patients recovered under the quinine without injections). Occasionally a diarrhea mixture was employed if intestinal irritability continued after the reappearance of bile. If irritability with foul odor persisted, a mixture of equal parts of sulphophenolates of zinc, calcium, and sodium was used at intervals of from two to four hours.

The Lancet, January 20, 1906.

Primary Pneumococcus Peritonitis.—The patient of W. C. Ashdowne was a woman of twenty-nine years, with a history of abdominal pain, diarrhea, and vomiting at intervals for some two weeks before admission to hospital. The general abdominal condition was one of distention and tenderness, and finally it was decided to open the abdomen. Much gas was present and some pus, with here and there thick fibrinous deposits on various viscera. The patient died within twenty-four hours after operation. The pus removed at the time contained encapsulated diplococci and a pure culture thereof was obtained from it. The author has found records of thirty-one primary cases due to the microorganism indicated. The primary character of his own case was verified by autopsy. Cases have been recorded of peritonitis secondary to pneumonia or part of a general infection. An analysis is made of the features of the previously reported cases. Of the thirty-one, eight were operated on; nineteen died, four recovered. In the case above referred to there was a history of drug-taking to avoid pregnancy, and the irritation thereby set up may have led to a sufficient gastroenteric disturbance to allow of the passage of the infecting organism through the bowel wall.

The Relief of Certain Headaches by the Administration of One of the Salts of Calcium.—G. W. Ross alludes to a form of headache in which the following are the common features: (1) It is present and most severe on waking, and tends to lessen in intensity or altogether disappear in from one to six hours. (2) It usually manifests itself as a dull, heavy ache, or as a frontal or temporal throbbing. Less often it is occipital, vertical, or unilateral. Infrequently it is neuralgic. (3) In its most typical form it is exceedingly chronic, often of several years' duration, and most intractable. It also exhibits itself as the common occasional headache to which many people are subject (4) It is associated with a deficient coagulability of the blood. The subjects of the chronic form of this headache are usually of the lymphatic type. The expression is heavy and listless. The face is full and the eyes are often puffy. Some anemia is the rule, and it varies in intensity from a slight paleness to an actual chlorosis. The whole bearing exhibits mental and physical lassitude. He styles it the "lymphatic headache." It is characterized by pain after food, edema in face or extremities, shortness of breath, chillblains, or articaria, or neuralgia in varying combinations. Eleven cases are tabulated. For treatment the author prefers the lactate of calcium in dosage of 15 grains, with a dash of tincture of capsicum in chloroform water or camphor water, taken before meals. This salt is more palatable and better absorbed than is the more familiar chloride. The lactate combines well with bitters, iron, and strychnine, but not with alkalies or their carbonates. The bowels must be carefully regulated. Milk is advised. Shellfish, strawberries, etc., are contraindicated. Malt liquors and wines are to be avoided. The author suggests that this plan of treatment for migraine, those neuralgiæ accompanied by a deficiency in the coagulability of the blood, and for some cases of chronic nephritis.

Bradycardia and Cardiac Arrhythmia Produced by Depression of Certain Functions of the Heart.—A paper elaborately illustrated is contributed by J. Hay, who describes the case of a man of sixty-five years, who had a slow pulse for some two and a half years before coming under observation. He suffered from a disturbance of conductivity in the muscle cells of the heart in response to the nerve stimulus to contraction—or as the author styles it, "heart block." This was estimated by measuring the time between the auricular and ventricular systole, as recorded in the tracing of the venous pulse. The patient's pulse was down to 32 per minute. Later the conductivity became normal, but the "block" which persisted was found to be caused by depression of excitability. At certain times the pulse was simply slowed, while at other times it was arrhythmical. According to Hay, no similar case has been recorded. Atropin had a marked influence in increasing the frequency of the stimulus production, but had no influence on the power of conductivity. Sounds were heard during the diastolic phase of the ventricles; they were synchronous with the wave in the jugular vein caused by the systole of the right auricle. The assumption seems justifiable that the sounds were produced by the auricle in its systole. The depression of the conductivity and excitability of the myocardium was probably due to impaired metabolism, secondary to an insufficient blood-supply, the result of arteriosclerotic changes in the coronary arteries. The excitability of the musculature was unstable, possibly as a result of nervous influences such as mental excitement.

British Medical Journal, January 20, 1906.

Extreme Bladder Over-Distension.—In a man of eighty years, with some fever, brown tongue, bad breathing, ede-

matous legs, and congestion at the bases of both lungs, D. J. Hamman found a tumor reaching from the pubes to the xiphosternum. The abdominal walls were extremely tense and the skin showed signs of cracking. The urine had been dribbling for several days. As a catheter could not be passed, aspiration was performed and 260 ounces of urine were drawn off. The patient died with uremic symptoms in four days. The autopsy showed the bladder occupying the abdominal cavity up to midway between the umbilicus and xiphosternum. It was firmly adherent to the abdominal wall and the surrounding viscera, and could not be separated without tearing of its walls. The walls were very thin. The ureter and pelves of the kidneys were greatly dilated. There were no deposits or calculi in the bladder. The middle lobe of the prostate was found much enlarged and projecting over the vesical opening of the urethra.

Food Poisoning and Coma.—A case similar to that reported in this journal one week ago is mentioned by C. Mercier, whose patient was a woman who had given a lunch party and had eaten freely of confectioner's viands. In a few hours she was found comatose. When seen she was still comatose and writhing violently. Suddenly these movements culminated in most violent vomiting, succeeding which consciousness returned. The author thinks that the coma can scarcely be attributable to any presence of ptomaine or other poison in the blood, but must have been due to the mere presence of indigestible food in the stomach. Was it an exaggeration of the drowsiness, he asks, we are all apt to experience after a full meal? Sleep pushed to excess is coma.

Treatment of Arteriosclerosis.—J. Barr enumerates as the causes of this condition, lead, pressor agents acting on the circulation, alcohol, nitrogenous foods, age, sex, physical strain, cold, and race. Americans are, the author says, especially liable to arteriosclerosis. Treatment is considered under the headings of diet, mastication, exercise, baths, drugs (thyroid extract, iodine, adrenalin, citrates, benzoates, sulphates and sulphites, and chlorides). Most men and women eat far too much nitrogenous food. This should be replaced by fats and carbohydrates, including fruits. Buttermilk may be used sparingly, but it contains considerable lime, and it is a good plan to combine it with stewed fruits, which largely neutralize the effects of the lime. Food should be thoroughly masticated and insalivated. Exercise is valuable, but should be carefully regulated. There is no exercise for the right side of the heart like mountain climbing, but advanced years call for caution in this respect. Baths according to the Nauheim plan have frequently a favorable effect on the blood-vessels. The author says that he rarely prescribes digestive agents and hypnotics for this class of patients. If a man cannot eat or sleep there is something wrong with him—he requires to be treated, not palliated. In this disease the man eats too much, and when his digestion fails he can readily subsist on some hot water until his appetite returns. In these cases insomnia depends on high blood-pressure, from whatever cause arising, and it is much better to remove the cause than treat a symptom. In the hands of the author thyroid extract has acted well as a vasodilator. Adrenalin—injurious alone—sometimes does good when combined with iodine or thyroid. Benzoates are of value when the kidneys are involved. As the chlorides are pressor agents, their use should be limited.

The Significance of Small Quantities of Sugar and Albumin in the Urine.—This question is considered by R. W. Burnet, who asks whether these cases of slight albuminuria or of glycosuria are not, in some instances at least, related to those showing signs of actual disease; whether, indeed, in some, it is only a question of the different stages of the clinical history; whether, in other words, permanent pathological changes do not in some cases develop or become evident later on. Both the albuminuria and glycosuria may arise under similar circumstances. The patients are apt to be those in whom, by reason of strain, of long-continued severe mental exertion, anxiety, or other such cause, the metabolic processes have been disturbed, the digestive functions have become disordered, and the nutritive activities seriously hampered, with the result that the patients are more or less out of health, although most probably one cannot put the finger on any definite sign of actual organic disease. The author is not disposed to accept the justice of the term "physiological" albuminuria. He denies the existence of any such condition. Normal urine contains no albumin. All albuminuria is therefore pathological. It is true that many of these cases seem to remain perfectly well, and unless we have evidence of increased arterial tension, casts, etc., we need not take too serious a view of these cases. Most of them do well, but the author believes that under unfavorable conditions a certain number drift into organic disease. Sugar indicates a more serious bodily disturbance than does albumin, especially if the former occurs in young persons. It is of less grave significance when occurring in the elderly. In the latter, with glycosuria we are apt to find free living and a large consumption of alcohol. Finally, the author states that the presence of both albumin and of sugar in the urine indicates serious disturbance in the metabolic processes, calling for relief to the nervous strain which the patient may have been undergoing, and an adjustment, as far as can be, of his environment, but that under favorable conditions these patients may continue in at least fair average health for many years.

Berliner klinische Wochenschrift, January 5, 1906.

Bilateral Empyema.—Laache maintains that this condition is not as rare as it is usually stated to be. Hellin, in a recent publication, reported that he had been able to find records of only 114 cases in the literature, but he, like the author expressed the view that the condition was commoner than ordinarily supposed. Laache describes two instances of this sort which have come under his own observation. The first case was that of a man twenty-one years old, who, after a lobar pneumonia, developed a purulent exudate first on the affected side and then also on the other. The second thoractomy was performed about six weeks after the first, and the patient was discharged cured at the end of about four months after the beginning of his illness. A noteworthy incident was the fact that in the course of one exploratory puncture the lung was evidently injured by the needle, as profuse hemoptysis amounting to 500 grams in twenty-four hours resulted, and a very large superficial hematoma developed, but the incident did not prove to be a serious complication. The other patient was the victim of extensive suppurating foci as the result of actinomycotic infection, and at the time of his death presented a double purulent pleuritic exudate.

The Forensic Identification of Blood.—Neisser and Sachs speak highly of the value of their method of blood identification by hemolysis, which they have now been able to test in three medicolegal cases. The delicacy of the method is so great that a perceptible reaction is produced even in dilutions of one to a million or one to ten millions, while in point of accuracy the procedure is comparable to the precipitin method. The test is carried out as follows: By a preliminary test the dissolving power for sheep's blood of the normal rabbit serum to be used is determined; the average figure for this being 0.25 c.c. to 1 c.c. of a 5 per cent. dilution of sheep's blood. This amount of the rabbit serum is then mixed with the solution to be tested for human blood and 0.01 c.c. of rabbit antiserum adapted for human blood is added. This mixture is kept at a temperature of 37° C. for one hour, and then 1 c.c. of a 5 per cent. dilution of sheep's blood is added and the preparation returned to the thermostat. At the end of two hours the reaction will be complete. If human blood was present in the suspected fluid no hemolysis of the sheep's corpuscles will have occurred, whereas in the absence of human blood hemolysis will have taken place. A control preparation exactly similar to the first except in the omission of the suspected fluid should show hemolysis. The authors recommend that this test be carried out in addition to the precipitin reaction in all cases in order to strengthen the evidence obtained, by the use of a second means of determination.

Münchener medizinische Wochenschrift, January, 16, 1906.

Pyelography.—Voelcker and Lichtenberg under this name describe the process of taking *x*-ray photographs of the pelvis of the kidney. In order to do this, the ureter is catheterized and the instrument is advanced until it has reached the renal pelvis. A 5 per cent. solution of colloidal silver is then slowly injected through the catheter by means of a suitable syringe until the patient complains of pain. There are marked individual variations in the amount of distention that the pelvis of the kidney will tolerate; thus, in one instance, the injection of five c.c. gave rise to severe colicky pains, while in other instances fifty to sixty c.c. could be introduced. The *x*-ray photographs are taken by means of Albers-Schoenberg's screen, and are said to be of satisfactory clearness. The authors have employed the method in eleven instances, ten of the patients being women and one a man. Four failures are recorded, owing to various causes. Schematic drawings indicating the noteworthy features of four of the radiographs are appended, and show dilatation of the renal pelvis, angulation of the ureter, and dilatation of the ureter. The authors believe that the procedure will be found of use in the diagnosis of displacements of the kidney, dilatation of the renal pelvis, disorders of the ureter, and perhaps of renal tumors also. The operation is not very painful, but is best preceded by the injection of a small amount of morphine.

The Diagnosis of Gallstones.—Ehret says that he has found that stones chronically impacted in the common duct give rise to a definite symptom complex which, when present, enables the diagnosis to be made with certainty. Two postulates form a desirable but not essential preliminary, first, the undoubted evidence of the existence of gallstone disease, and, secondly, the at least occasional coloration of the stools with bile pigment. The author's symptom com-

plex comprises three elements. The temperature is usually normal, but at more or less regular intervals periods of fever appear, to be followed by a return to normal lasting from a few days to several weeks. The elevation of temperature may reach 41° C., and lasts for one or two days, after which it returns to normal by crisis. These periodical elevations of temperature are regularly accompanied by a deepening of the already existing jaundice. In those patients who are not habitually jaundiced, icterus appears at these times. When the temperature goes down, the coloration of the skin also returns to the condition usual for the patient. The third element consists in the fact that although the liver may be sensitive to pressure, these periodical attacks are usually not associated with any noteworthy subjective disturbance, the pain ordinarily present in cholelithiasis being conspicuous by its absence. The author affirms that while every case of stone in the common duct may not give these symptoms, in every instance in which this triad does occur the existence of a stone impacted in the region indicated may safely be assumed.

The X-Ray Examination of the Stomach and Intestine.—Rieder speaks very highly of the advantages to be derived by the use of the *x*-ray in determining the position and conformation of the stomach and other portions of the alimentary tract, and states that valuable information in regard to their functional efficiency may also be obtained in this way. The simplest method of procedure is to have the patient drink about fifty c.c. of water to which ten or fifteen grams of subnitrate of bismuth has been added. The patient swallows the mixture under observation by means of the fluoroscope, and useful information in regard to the esophagus and stomach is often secured. The act of swallowing may be studied more at leisure if a small quantity of the bismuth salt is given in a capsule or as a species of dough by mixture with a small amount of water. If more exact observations on gastric motility, or intestinal activity, etc., are desired, a bismuth meal may be employed. To prepare this, about thirty grams of subnitrate of bismuth are mixed with a little milk, and this is then added to 300 to 400 grams of flour gruel, sweetened with a milk sugar in order to obviate the tendency to constipation. In order to study the conditions existing in the large intestine, rectal injections containing bismuth may be administered, and the author has found that by the use of one liter of fluid it is possible to insure penetration as far as the iliocecal valve. The author also points out the various ways in which this method of examination may be utilized for diagnostic purposes in cases of gastric affections, such as hour-glass stomach, gastroptosis, dilatation of the stomach, intestinal stenoses or obstruction, dilatation or descent of the colon, the differential diagnosis of tumors, etc. Although ordinarily the observations are most satisfactorily made by means of direct inspection with the fluoroscope, instructive radiographs may also be secured as in any other department of *x*-ray work.

Deutsche medizinische Wochenschrift, January 18, 1906.

The Dietetic Treatment of Gastric Ulcer.—Senator first mentions the plan of treatment for gastric ulcer employed by Lenhartz, who advocates giving the patients small quantities of very concentrated food, such as eggs, from the first, and rapidly increases the diet by the addition of sugar and milk, and gives scraped beef as early as the end of the first week. The idea of this treatment is to maintain the patient's bodily strength and prevent the doubly weakening effect of hemorrhage and starvation. Senator occupies a middle position between the views of Lenhartz and the older plan of starvation treatment, and recommends a dietary which will be nourishing but also non-irritating, easily digestible, concentrated, and tending to check hemorrhage. This consists in the use of gelatin, fat, and sugar. The first step is the administration of 10 per cent. sweetened gelatin solution, which is given in tablespoonful doses at intervals of from a quarter of an hour to two hours. Small amounts of fresh butter and cream are also allowed, the butter being preferably given in little frozen balls, and the cream beaten up with sugar so as to form the ordinary whipped cream. The daily allowance of this dietary is equivalent to 900 or 1,000 calories, and it may be begun even immediately after a hemorrhage. The gelatin solution may after a time advantageously be replaced by more palatable forms of the same material, such as calf's foot jelly, or other varieties. Other therapeutic measures are also employed, and in some instances rectal feeding may be resorted to, though of late years the author has found little occasion to use the latter means of feeding.

French and Italian Journals.

Sudden Death at the End of Pregnancy, Post-Mortem Cesarean Section, Living Child.—P. Rudaux reports two cases of this nature. The first patient described was a woman, twenty-eight years old, without any pathological antecedents. She had become pregnant for the first time when twenty years old, and had given birth at term to a male child. She became pregnant again in 1898. She entered the hospital in February, 1899, a short time before labor was due. A few days later she died suddenly. Every effort was made to resuscitate her—artificial respiration, traction of the tongue, subcutaneous injections of ether and of caffein were all practised, but in vain. The heart beat persisted, but was becoming feebler. Cesarean section was performed and a living child extracted. The urine had always been normal. At autopsy the lungs were found to be congested, and the right ventricle contained a large blood clot which extended into the infundibulum. The kidneys were of normal size and of dark red color. The liver was large and of dark color. The spleen was soft. There was nothing in the brain of any interest, neither did the uterus present any lesion.—*Annales de Gynécologie et d'Obstétrique,* December, 1905.

Hygiene of Nurslings.—H. Méry draws attention to the increasing interest which is being taken in the study of infantile conditions. He emphasizes the importance of distributing, not plain milk, but modified foods which are found after examination of the child to be indicated by its condition. There are various institutions which devote their energies to the distribution of plain foods, but the distribution of such foods as buttermilk, modified milk, and so on, should be looked after. Méry thinks that as few children as possible should be kept in the hospitals. He believes in encouraging outdoor consultation for sick nurslings, and in distributing pecuniary aid to the mothers. A house in which the régime of nurslings could be looked after exclusively would be most appropriate for this work. This building should have its various laboratories, and bacteriologists, for the preparation of fermented milks of various kinds. A most important department would be a culinary laboratory, which should be taken care of by a person who is capable of directing it. A convalescent home outside of Paris would also serve a good purpose in the care of these children. When the children are admitted to the hospital the writer believes that all those who have any contagious disease should be strictly isolated from those who are suffering from simple digestive troubles only and who need only dietetic treatment. The writer believes that if these suggestions were carried out, the mortality of children would be decidedly decreased.—*La Presse Médicale,* January 6, 1906.

Indications for Surgical Treatment of Diseases of the Stomach.—Queirolo says that in matters of diagnosis and therapeutic indications, diseases of the stomach are essentially inside the domain of internal medicine; surgery is the arbiter of the possibility and value of operative interference in special cases. The determination when surgical interference shall take place belongs to medicine, because of its observation of the symptoms bearing on diagnosis, and its knowledge of the probable utility of any operation performed. In gastric ulcer, when it is rebellious to medical treatment, we may turn to surgery to do an excision or to change the form of the organ, or the margins of the ulcer. There are peremptory indications for surgical interference in cases of complications, such as repeated hemorrhage, perforation, or stenosis of the pylorus, as a result of cicatrization. In atony and gastric dilatation, when medical treatment is seen to be useless, a gastroenterostomy is indicated. In pyloric spasm, long duration of the disease, without medical relief, favors surgical interference; the dilatation of the organ and the general decay of nutrition also indicate it. In pyloric hypertrophy, when the disease is of long duration, and rebellious to rigorous measures, gastroenterostomy is a factor in the cure of the affection.—*La Riforma Medica,* December 23, 1905.

Intoxication Arising from Medication in Babies.—R. Jemma tells us that some children show a remarkable tolerance for drugs, and can take larger doses than adults in proportion to their age. At the same time, others have symptoms of intoxication from therapeutic doses of ordinary drugs. Some authors publish series of cases of remarkable tolerance for opiates, while others record other series of deaths from small doses of the same drugs. The author believes that these apparent contradictions are an indication that individual idiosyncrasy plays an important part in the matter. He records one case of intoxication from antipyrin, given for a spasmodic cough in ordinary doses, where the mother gave the entire bottle at one dose. The child was taken with intense dyspnea, vomiting, congestion of the face, and severe spasms of coughing, with bloody expectoration. The following day it had a typical antipyrin rash, part of it purpuric. Another case observed by him was the result of chocolate tablets of an anthelmintic, believed to be santonin. The child suffered from prostration and torpor, eclamptic seizures, and deep yellow coloration of the urine. He had taken only two of the tablets, probably three to ten centigrams of santonin being taken in all.—*Rivista di Clinica Pediatrica,* December, 1905.

Book Reviews.

Materia Medica and Pharmacy. By Reynold Webb Wilcox, M.A., M.D., LL.D., Professor of Medicine at the New York Post-Graduate Medical School and Attending Physician to the Hospital; Consulting Physician to the Nassau Hospital; Visiting Physician to St. Mark's Hospital; Ex-President of the American Therapeutic Society; Fellow of the American Academy of Medicine; Vice-Chairman of the Revision Committee of the United States Pharmacopeia, etc. Sixth Edition. Based on the Fifth Edition of White and Wilcox's "Materia Medica and Therapeutics." Philadelphia: P. Blakiston's Son & Co., 1905.

The changes rendered necessary by the issue of the recent edition of the United States Pharmacopeia, and the accumulation of matter that has been from time to time added to the various editions of "White and Wilcox" have induced the editor to rewrite the work. The present volume is the first part of this revised work, and contains Materia Medica and Pharmacy. The preparations, doses, and descriptions of the remedies are given in considerable detail, and there is a useful résumé of the action and uses of the drugs and preparations. Therapeutics and Pharmacology will be treated of in detail in another volume. Both official and unofficial preparations receive similar recognition and attention; the latter, indeed, taking up an appreciable part of the volume. The book is well printed and has a very complete index.

Practical Sanitary Science. By David Sommerville, B.A., M.D., Lecturer in Public Health, King's College, London. New York: William Wood & Co., 1906.

This is an excellent little handbook for the public health laboratory, containing as it does, between its covers, an outline of practically all the important methods of sanitary examination concerned with the analysis of water, air, soil, sewerage, foods, and disinfectants. Though intended primarily for students, the book can be commended to health officers for ready reference. While the methods described are few, yet they are sufficient in number to meet any ordinary condition, and in character are such as have been approved by the test of long practical employment.

The Surgeon-Generals of the Army of the United States of America. By Major James E. Pilcher, U. S. Vols., Captain U. S. A., retired. Carlisle, Pa.

This book, as its name indicates, consists of biographical sketches of the official heads of the Army Medical Department since its organization in the Provincial forces before Boston. The book is a collective reprint of the series of essays on the subject appearing from time to time in the Journal of the Association of Military Surgeons. The work covers a field of medico-military history hitherto unoccupied, and in its style, completeness, and make-up, reflects much credit on the author.

A Text-Book of the Diseases of the Ear, Nose, and Pharynx. By D. B. St. John Roosa, M.D., LL.D., Professor of Diseases of the Eye and Ear in the New York Post-Graduate Medical School and Hospital, etc., and Beaman Douglass, M.D., Professor of Diseases of the Nose and Throat in the New York Post-Graduate Medical School and Hospital, etc. New York: The Macmillan Co., 1905.

This work by two well-known teachers and clinicians well illustrates the modern idea of the intimate relation between aural and nasal diseases. In fact, one chapter of eighty-three pages is devoted to diseases of the nose and nasopharynx which may affect the ear. To quote from the preface: "The recent proper estimate of the relation between the nose and ear has led us (the authors) to endeavor, not merely to place these subjects in one volume, but to weave them together as one subject, thus emphasizing their common dependence." This is the keynote of the work and the standpoint from which it is written.

A distinctly conservative line pervades the various chapters. The chapter on acute inflammation of the middle ear is full of common sense. Great stress is laid upon the necessity for prompt and efficient treatment of the milder conditions so as to avert the more serious ones and thus obviate the need of major surgery. Concerning the popular use of electricity for the relief of eustachian obstruction, it is declared that nothing is accomplished by it that is not achieved by the use of common air, medicated vapor, and bougies. We are rather surprised to find no mention made of the submucous resection of the nasal septum for deviations. The preface opens with the statement that the book is intended to assist practitioners and students of medicine to study and treat diseases of the ear. This result has, we think, been attained with a most gratifying success.

Lo Sgombero degli Ammalati e dei Feriti in Guerra. Memoria dei Dottori Luigi Bernardo, Tenente Colonn. Medico, e Guiseppe Brezzi, Maggiore Medico, Onorato dal° Premio nel Concorso Riberi del 1902-1903. Rome, 1905.

This monograph on the care and transportation of the wounded in the field of battle received the first prize of the Medical Department of the Italian army in 1904. It deals with the means of transporting the sick and wounded from the battlefield to places where treatment can be properly carried out; and with the care of the wounded on the battlefield under various conditions and in different countries. The authors consider first, the effect of transportation upon various injuries of warfare; then they go on to the art of estimating losses in battle, and the manner of handling and transporting the wounded during the battle. They study, especially, the surgical service of the Anglo-Boer war, and draw therefrom conclusions for the guidance of the Italian and foreign armies in the future. They discuss in detail the organization of transportation facilities, and the means of first aid on the battlefield. Charts are appended, geographically illustrating the disposition of the corps of surgeons, the arrangement of field and base hospitals, etc. during a conflict. The monograph should be translated into all languages, and would have done much good in the Russian army during the war just closed.

The Art of Massage. By A. Creighton Hale. Second Edition (Fifth Thousand). Profusely Illustrated with Original Drawings. London: The Scientific Press, Limited.

This book contains twenty-seven chapters and treats of massage and incidentally of several other things. The parts dealing with massage may possibly be of some service; those devoted to the etiology and treatment of disease are not satisfactory, and seem out of place.

Materia Medica and Therapeutics. An Introduction to the Rational Treatment of Disease. By J. Mitchell Bruce, M.A., LL.D. (Hon.) Aberd., M.D. Lond., Fellow of the Royal College of Physicians of London, Consulting Physician to Charing Cross Hospital and to the Hospital for Consumption, Brompton. Formerly Examiner in Medicine in the University of Cambridge, and Examiner in Materia Medica in the University of London and in the Victoria University. New and enlarged edition, revised throughout, and containing the Indian and Colonial Addendum to the British Pharmacopœia. Forty-seventh Thousand. Chicago: W. T. Keener & Co., 1905.

In the present edition of Bruce's Materia Medica and Therapeutics the subject matter has been revised and brought up to the level of the latest knowledge. There has also been added a new part containing an account of the Materia Medica of the drugs in the Indian and Colonial Addendum to the British Pharmacopœia. The book is very little larger than the former editions, and on account of its accuracy and general trustworthiness will continue to be a favorite with students and practitioners using the British Pharmacopœia. The section on therapeutics is particularly valuable, the subject being treated on a physiological basis, and appealing to the reader by its concise and logical methods.

Surgical Diagnosis. A Manual for Students and Practitioners. By A. A. Berg, M.D., Adjunct Attending Surgeon to the Mt. Sinai Hospital, New York. New York and Philadelphia: Lea Brothers & Co., 1905.

It may truly be said that the favorable light in which modern surgery appears is due as much to the development of means for making an early diagnosis as to the actual improvement in operative technique. Pathology, bacteriology, chemistry, and physics have all contributed to an early and correct recognition of maladies which should be regarded, and in fact are, surgical in character from their incipiency. But few diseases now remain for which some means of early diagnosis have not been devised. In the present work the attempt has been made to bring together in a concise fashion the essentials of all surgical diseases, with the exception of those of the eye and ear, giving in each case a general clinical picture, including the etiology, the course of the disease, and sometimes the pathology. The differential diagnosis is also stated in some instances, but this feature might have been developed with advantage. The chapters on surgical diseases of the abdomen and on diseases of the urinary organs are very complete, and in the latter the value of cryoscopy and cystoscopy is fully discussed. The original illustrations, including the *x*-ray pictures, are very good; most of the others have a familiar, hackneyed look, and many appear somewhat the worse for wear. The book constitutes an efficient and fairly comprehensive manual and forms a worthy addition to the very few English books on this subject which we possess.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 21, 1905.

Dr. Charles L. Dana, in the Chair.

This meeting was held under the auspices of the Sections in Medicine and Genitourinary diseases.

The Treatment of Gonorrheal Rheumatism with an Antigonococcus Serum.—Dr. John Rogers read this paper. He said that from what was known of other infectious diseases it was very evident that the prolonged cases of this infection must lack the antibodies which naturally existed or were produced in the vast majority of individuals, and if these antibodies could be provided artificially recovery might at least be accelerated. There was still doubt as to how the human urethra recovered from the infection, but it seemed explainable on the ground that the mucous membrane gradually became an unsuitable culture medium. The injurious effects of the infection were probably produced not by a true toxin, but by a bacterial proteid which was liberated by the death of the organism. The term gonorrheal rheumatism seemed particularly appropriate, as by analogy it called attention to the systemic infection which most commonly manifested itself by serious disease of one or more joints and less often involved other organs. It also invited comparison with the ordinary acute polyarticular rheumatism, in which the microbe cause of the almost exactly similar lesions was as yet not proved. After entering the circulation the gonococcus showed a marked affinity for the serous membranes, and in addition to the common disorders of joints and tendon sheaths which it produced, there were enough cases of endocarditis, pericarditis, pleuritis, and meningitis due only to the gonococcus on record, to make one attribute to this organism any such complication in a patient giving a more or less recent history of gonorrhea. One or more of the large joints might be attacked at almost any period after the incidence of the gonorrhea, the usual time being between the first and eighth week. After considering the symptoms, the differential diagnosis, prognosis, etc., he said the ordinary antirheumatic treatment was notoriously unsatisfactory. In every suspicious case from 20 to 60 minims of the antigonococcus serum should be administered every day or every other day beginning as early as possible after the arthritic symptoms appeared and continuing until the pain and disability subsided. He usually gave it in the loose tissue overlying the fascia in the back of the upper arm. There was generally a noticeable improvement at the end of twenty-four or thirty-six hours, and within a week or ten days an almost complete subsidence of the disorder if it was acute. After the suspension of the treatment there seemed to be a constant danger of recurrence or recrudescence of the arthritis, especially if the urethritis persisted and the inoculations might have to be repeated. But the whole course of the disease was vastly shortened and ameliorated and, beyond an occasional arythema, absolutely no ill effects had been produced. This method of treatment had the same limitations and disappointments of all serum therapy and was not advanced as an infallible remedy. The effectiveness of the serum depended to some extent upon the animal and the culture which was used, the length of time and the manner and this animal was inoculated, and the number of "bleedings" to which it was subjected. The serum had little or no effect upon the urethritis. The unfortunates who suffered from gonorrheal rheumatism must have a constitutional deficiency of antibodies, and as soon as these were supplied artificially the disease subsided. He submitted the histories of eight cases, which were examples of the common acute, chronic, or prolonged forms of this joint disease, and although they were by no means all that had been tested, he had not omitted the failures. In a "prolonged" case, or one which persisted for years and years, and from bad to worse, a failure should not be judged harshly when the possibility of error in diagnosis was considered. Many good observers doubted the existence of such a condition, and its explanation involved some difficulties. But in following the histories of these patients the more or less steady continuation of the same milky inflammatory process seemed to him conclusive evidence of the nature of the original infection, even if its definite prolongation was due to some superimposed alteration in nutrition or metabolism. That one of these peculiar cases was evidently benefited was certainly gratifying and encouraging.

Preparation of an Antigonococcus Serum Effective in the Treatment of Gonorrheal Rheumatism.—Dr. John C. Tarrey said there were several reasons why an antigonococcus serum had not been used heretofore in the treatment of gonorrheal rheumatism. It had been found to be impossible to bring about an infection in animals by the gonococcus. Again, there was not the slightest indication of an acquired immunity in man to gonorrheal infection. Finally, the consensus of opinion seemed to be that animals could not be immunized to the toxin of gonococcus as it was contained within the cell. It was, in other words, an endotoxin, a bacterial protein. Although there was apparently slight chance of success, at the suggestion of Dr. Rogers, he prepared a serum for a case of gonorrheal rheumatism of some fifteen years' standing, which had been treated in every other way without result. They were agreeably surprised to find the serum effective not only in that case, but also in a high percentage of others on which it had been tried. The culture, which was originally employed in producing the serum, was isolated from an acute case of gonorrhea in a male. It conformed in every respect with the characteristics of the gonococcus. The diplococci were negative to Gram's stain, would not grow on ordinary peptone agar or broth, and died on ascetic sugar in a short time. For purposes of inoculation a very satisfactory medium was a mixture of rich ascetic fluid and slightly acid beef infusion peptone broth. The incubator temperature should be between 36° and 37° C. This strain, after being cultivated on artificial media for over a year, grew fully as well and produced practically as effective a serum as when first isolated. Two other strains of this organism, kindly given him by Dr. Elser, gave rise to fully as potent a serum as the original culture. Rabbits had been used exclusively in producing the serum. They should be inoculated every five or six days, intraperitoneally, with 10 c.c. of culture. The best results were obtained with cultures from six to fifteen days old. The highest degree of toxicity and growth was obtained during this period. The first inoculation always caused a great loss of weight, sometimes one-fourth the total weight. The five or six days following inoculations gave rise to only a very slight loss of weight and discomfort. After a variable time, however, the majority of the rabbits reached a condition of hypersensitivity to the toxin and succumbed to a dose that would never have proved fatal to a normal animal. This seemed to indicate that the toxin present in the culture medium was, for the most part, if not entirely, derived from the dead bodies of the cells. Only exceptionally did rabbits approach a condition of active immunity. The animals were bled from the ear or the carotid. Serum derived from the later bleedings was more potent than that obtained at first, when the animal had received only a few inoculations. The serum kept well on ice for two or three months. In inoculating rabbits whole cultures, both the cells and filtrate, were used, with the hope that a serum might be obtained possessing both antitoxic and bactericidal factors. That it was at least in some degree antitoxic seemed probable from its protective power for guinea pigs. The chemical evidence also pointed to the same conclusion. The more important permanent benefit which the serum in most cases afforded was, without doubt, however, due to a bactericidal activity. It seemed probable that the serum supplied enough immune

bodies to enable the system to destroy the comparatively few gonococci which were concerned in gonorrheal rheumatism. This supposition had not been substantiated as yet by complete experimental evidence. Both agglutinins and precipitins for the gonococcus had, however, been demonstrated in the serum.

Dr. James Ewing discussed the paper.

Deductive Value of Urinary Examinations.—Dr. Richard C. Cabot of Boston in this communication said that in the study of diseases of the kidney we were still hampered by the tyranny of the morphological point of view which was, like most tyrannies, self-imposed. We had formed the mental habit of asking what the diseased organ would look like if we could see it at this moment. But it should be remembered that it was *functions* and not appearances that deserved our main interest. Renal irritation and renal insufficiency, acute and chronic, was what we wanted to recognize and to treat. Three sets of changes must be distinguished in the kidney as follows: Renal irritation, which showed itself in the presence of albumin and casts; renal insufficiency, which might exist with or without albumin and casts and showed itself chiefly in the physical characteristics of the urine and in the condition of the rest of the body; and nephritis, which showed itself in the post-mortem appearance of the kidney. The very wide and important discrepancy between urinary findings and post-mortem appearances had been very forcibly borne in upon him by his own investigations, as well as others.

Renal irritation was most easily studied in that produced by violent muscular exertion, *e. g.* a boat race. The urine in such cases almost invariably contained serum albumin and casts, the former being even as much as ½ per cent. and the casts as numerous and as various as in acute nephritis. After a few days' rest all abnormalities disappeared from the urine. The largest number of casts ever seen by Drs. Cabot and Emerson occurred in cases of diabetes with sound kidneys post-mortem. What he wished especially to emphasize was that the evidence of irritation, albumin and casts was not evidence of nephritis, which might be or might not be present. Hence the folly of sending a urine to the laboratory or to a urologist for diagnosis, or for more than a description of what he found.

If the kidney could not do its work, if it could not excrete the products of nitrogenous metabolism, or if it could not excrete water and the inorganic salts, definite changes could be found either in the urine or in the functions of other organs, uremia, dropsy, and cardiac changes. The mutual dependence of heart and kidney was almost as close as that of stomach and bowel. A strong heart would pull the system along, even if the kidney was badly damaged. The harm done by a diseased kidney seemed to depend in many cases on how well the heart could make up for the damage by increased work, and, in such cases, one got characteristic changes of renal insufficiency. These were to be appreciated by (1) the changes in the physical characteristics of the urine and (2) by that group of changes known as uremia, dropsy, and cardiac enlargement. Evidence of irritation (albumen and casts) or change in the amount of this or that solid excreted might or might not accompany the gross physical evidence on which our knowledge of renal insufficiency depended. The physical changes were so familiar that he enumerated them in the briefest manner. When conditions permitted the test by quantitative analysis, which substances were retained and which were excreted was direct functional diagnosis and should be of the greatest value in therapeutics.

Regarding nephritis the reader quoted from Dr. Emerson's figures as follows: "Out of 11 cases of extreme chronic passive congestion without any microscopical evidence of nephritis, 8 were diagnosed clinically as nephritis. Thirteen out of 109 cases of acute nephritis were recognized first at autopsy, while 11 were called acute nephritis clinically, but not at autopsy. One in every four was wrongly diagnosed." In 46 out of 104 cases of chronic indurative nephritis (43 per cent.) the diagnosis was not made in life. Scanty urine, even anuria, or at the other extreme, polyuria with low gravity, might exist without nephritis; it was the persistence and not the existence that was a serious matter.

The following were the reader's conclusions: (1) Functions, not histological appearances, were what one should strive to recognize in kidney disease. (2) Albumin and casts never meant nephritis; they might, or might not, accompany it. (3) The physical characteristics of the urine, the visceral evidence of uremia, dropsy, and cardiac involvement were the best helps to the functional diagnosis of renal disease. The dilution test, the concentration test, and, if opportunity offered, the quantitative estimate of the kidney capacity to excrete particular substances might render valuable aid.

The Medical Treatment of Diseases of the Kidneys.—Dr. James Tyson of Philadelphia said that indications for successful treatment of kidney disease were (1) to restore the kidney to its natural condition and (2) to overcome such dangers as threatened the economy. The means to these ends were not as simple as the statement of them, but they were more easily met in acute than in chronic nephritis. In acute nephritis the condition of the kidney was more favorable for recovery to the normal state if rest was enjoined, especially rest in bed. Then the patient should not be given such food as would tax the kidney function. Such food as milk, or milk and water, or vichy or carbonated waters were of value. Again the kidney might be depleted by purgation, as a saline purge or calomel. These three measures fulfilled the indications for the treatment of the vast majority of cases of nephritis. But there were two symptoms at least which should be considered, dropsy and uremia. Fortunately, the same treatment which was involved in the fulfilment of the first acted in the fulfilment of the second condition. Purgation should be repeated and persisted in. Sweating produced by vapor baths, or hot-air baths, or other methods should be employed. He placed sweating after purgation; elimination by purgation was more efficient than elimination by perspiration. By the employment of such measures the majority of the cases of simple acute nephritis would get well. The measures employed in the treatment of the acute cases should be continued in the chronic cases and with two additional ones. First, the administration of hot-water injections high up in the rectum; secondly, the subcutaneous or intravenous injection of saline solutions. His own experience with these remedies or with high injections was not satisfactory, great difficulty being in getting the liquid to stay. The rectum should first be washed out. It was supposed to act well in exciting increased excretion of urine. Hypodermoclysis was sometimes of value in the treatment of uremia, but it should never be employed except in association with venesection and so avoiding the overfilling of the right heart. If one should first bleed the patient and then introduce the saline solution, so diluting as well the toxins, good should accrue. The employment of diuretics in the management of these cases hold a secondary place. They should not be used until sweating and purgation have first been practised. In the large majority of cases it was almost impossible to make a diagnosis between chronic interstitial nephritis and chronic parenchymatous nephritis. In the management of these chronic cases he said there was no drug that had the power of influencing these chronically inflamed kidneys, and this was a fundamental proposition. There was no one drug which could influence an albuminuria. In such cases rest became an important adjuvant, but because the disease was such a prolonged one it was a disadvantage, because of the long confinement and want of exercise; this more than counterbalanced the good that might result from the rest in bed. A patient might be placed at rest for fully a month or six weeks if massage were employed; such a plan might

lower the amount of albumin even one-half or one-quarter, but it would not reduce it entirely. In the treatment of these chronic cases one should attempt to find a golden mean as regards the question of rest. Dr. Tyson referred to another class of patients who came for life insurance examinations, not aware that the urine contained albumin and casts, the discovery being made accidentally. In such cases he advised no treatment whatever, except to caution the patients to lead restful lives and to carefully select their food. He asked what should these cases of chronic nephritis live upon? In the first place milk was always a safe diet, but should be given only to the extent of one quart a day. After this came vegetables, such as the soft and succulent ones, like potatoes, rice, beans, and tomatoes. Cereals and sugars he had been surprised to hear physicians make injunctions against. There was no reasonable objection whatever to nephritic patients having sugar in ordinary amounts; there was no more suitable diet than sugar in moderation. Meat in moderate quantities should be allowed. The most important thing to consider in the dietetic treatment of chronic nephritis was quantity. One should not encourage overfeeding, but moderation in eating, as well as in all things. It did not make so much difference what patients ate except from the standpoint of indigestion. Crisp bacon might be allowed in the middle of the day and raw oysters in the evening. Eggs should be allowed, but one should watch for idiosyncrasies, and if it was found that the consumption of eggs increased the albumin, they should be discarded. Alcohol was capable of producing a nephritis, therefore he did not advise its use in nephritic cases; yet there were cases in which alcohol seemed to do good in moderate amounts, particularly prior to meals as an appetizer, as a cocktail before, and possibly whiskey and water with meals. Condiments he considered to be harmful, especially horseradish. Coffee, tea, and tobacco fell in the same category with alcohol; that was, their moderate use was not necessarily harmful; they became harmful only when they were abused. Regarding drugs he said that more harm than good was done by their use in chronic nephritis. To produce an increased excretion of urine he preferred citrate of potassium. Iodides were also to be recommended in some cases when accompanied by arteriosclerosis. Iodide of sodium in small doses, continued over long periods of time, had given good results in these cases. But so soon as the first evidences of any harmful effects presented themselves the iodides should be at once stopped. The iodides seemed to act as diuretics. His experience had taught him that opium should never be used if it could be avoided. In the water-logged condition of chronic nephritis the same measures as above were to be employed, but with less prospects of success. Long incision, about one inch long, behind the ankles, followed by antiseptic dressings, was followed by far better results than the usual mere pin scratchings. The saddest of all the symptoms of chronic nephritis was the gradual appearance of retinitis albuminurica; here one met with the utter futility of treatment; such a condition showed that the end was not far off. To be sure some cases lasted a year, and even longer. Sometimes the biniodide or bichloride of mercury combined with the iodides had some effect in clearing up in a measure the loss of vision.

The Operative Treatment of Chronic Nephritis.—Dr. Ramon Guiteras presented this communication. He referred to the opinions of numerous surgeons in this country and abroad who were interested in renal surgery. Two and a half years ago he sent out a communication to 150 of the most prominent surgeons of this country, and he found that they were about equally divided in favor for and against the Edebohl's operation of decapsulation. Answers were received from 42 surgeons who had performed the operation, the aggregate number of cases operated on being 120. Of these 120 cases 16 per cent. were reported cured, 40 per cent. improved, and 11 per cent. unimproved; of this list there were 33 per cent. deaths. In cases of interstitial nephritis the results appeared to be brilliant, as the albumin and casts disappeared from the urine, although the amount of solids excreted was not brought up to the normal. The mortality in cases of chronic interstitial nephritis unfortunately was 26 per cent.; in chronic parenchymatous nephritis, 25 per cent; in chronic diffuse nephritis, 75 per cent. The operation of decapsulation for the cure of chronic Bright's disease was then a new procedure. Recently he sent letters to these same 42 surgeons, asking for later results of their operations. One-half of this number replied. They had decapsulated the kidney on 41 cases of nephritis, minus one case, which was a movable kidney and operated on by nephropexy. Of these 40 cases the report was as follows: Recovered, 1 patient; improved, 3; unimproved, 3; died, 33 (82 per cent.). Therefore the speaker felt that he was now justified in saying that at the present time capsulectomy was not a popular operation among the surgeons of the United States, while in Europe it had been thoroughly tried and had but few followers. It was difficult to see how decapsulation could be expected to cure such diffuse and deep-seated kidney disease as arteriosclerotic interstitial nephritis or diffuse parenchymatous degeneration of the kidney. The other operations for chronic nephritis were nephrolysis, nephrotomy, nephrectomy, and nephropexy. Nephrotomy was still the operation which appealed to most of the European surgeons in the treatment of chronic nephritis and was used in cases of hematuria, in the nephralgic type, to relieve the tension of nephritis, and for anuria. Personally, the reader did not believe in total decapsulation, but he was a firm believer in partial decapsulation of not over one-sixth of the kidney area to assist in fixation, if the kidney was movable. If the kidney was not movable he believed that tension would be removed by simply incising the capsule over the convexity. If there were symptoms of unilateral nephralgia and hematuria he would perform a nephrotomy not only as an approved operation, but also as an exploratory means of determining a possible existing surgical disease. In closing, he wished to emphasize the importance of making a correct diagnosis in renal disease, and in this one must be guided by the history, the general examination, and the urinary findings. In renal surgery it was not what one found, but what one did not find, that often influenced unfavorably these cases. Therefore, one should not be satisfied with anything less than a thorough routine examination in all the cases, and, if suspicions were aroused regarding a possible abnormal condition, one must exhaust every means to know its presence or absence. Too much haste and not sufficient study had heretofore been the two factors which had interfered with success in renal surgery.

Dr. Edward G. Janeway said that albumin and casts were dubious things on which to make a diagnosis; something more should be present to go on. Not only should one study the presence of albumin and casts, but other things as well, in order to make even a tentative diagnosis. He cited several cases, in order to illustrate certain points he wished to emphasize. In the water-logged condition the kidneys were taxed by placing too much water in the system. Opium made patients more comfortable, but there were times when it was productive of great evil. Cheyne-Stokes breathing was often quickly relieved by a hypodermic injection of morphine. Small doses of mercury would often cause salivation in these patients; this had been known to follow the use of Fothergill's pill. Iron should be used with great care.

Dr. George L. Peabody said he was largely in accord with what had been already stated, although he believed that Dr. Cabot was too radical, if he really meant to say that albumin and casts indicated nephritis. There was nephritis if there was a persistence of the albumin and casts. With regard to the treatment he was glad that Dr. Tyson had helped to do away with that bugbear of diet.

There was no question in his mind but that the diet in chronic nephritis should be a varied one to maintain the nutrition of the patient. There was another superstition regarding the use of red meat. These patients should have a reasonable amount of meat every day. The treatment of chronic nephritis resolved itself into the treatment of the symptoms. He referred to the fact that chronic nephritis and rheumatism was almost unknown along the Nile in Egypt. Certain climates appear to stimulate the renal excretion. The best means of relieving high tension, he believed, was venesection; next to that was aconite; next to aconite was chloral. In cases of chronic uremia with high-tension pulse, cardiac disturbances, and insomnia, aconite did well. Nitroglycerine was an uncertain agent; nitrite of sodium was more to be relied upon. In uremic convulsions he said he had had success with ethylcarbonate, but this agent should be given in large doses, hypodermically. The mineral waters he considered useless. He had had a limited experience with decapsulation of the kidney. He reported the case of a boy who had had decapsulation performed four times, and possibly might have to have it done again. Decapsulation was performed after all other methods had failed to relieve the anasarca; after the operation the boy was apparently well. But he had relapses, necessitating the operation again. He was now in the hospital under medical treatment; if this failed, the operation would again be resorted to.

Drs. T. W. Hastings and E. E. Smith also discussed the papers.

NEW YORK PSYCHIATRICAL SOCIETY.

Meeting Held December 6, 1905.

The President, Dr. Allan McLane Hamilton, in the Chair.

Insanity as a Result of Hysterotomy and Oophorectomy.—Dr. Graeme M. Hammond under this title discussed the doctrine of the influence of the ovaries upon mental development, and concluded that they did not supply the brain with any substance necessary for the preservation of its integrity, and that the removal of these organs was never followed by insanity unless there was hereditary tendency to insanity or a congenitally defective brain. He admitted that insanity more frequently followed operations upon the pelvic organs than any other operations, but stated that this was not due to the loss of the ovaries and uterus, but (1) to an hereditary tendency to insanity; (2) to psychical causes, such as the fear of death, disappointment at not bearing children, the curbing of the maternal instinct, the fear of the loss of the husband's love, the fear of becoming cold and indifferent to the husband, and the fear of acquired masculinity; (3) to physical causes, such as anemia, neurasthenia, and the breaking down of the general health from long-continued disease; and (4) to surgical shock. His conclusions were that insanity was not due to loss of function of the ovaries or uterus, and that insanity never followed operations on these organs unless there was an hereditary tendency to insanity or a congenitally defective brain, and that this tendency, developed by the psychical and physical causes referred to and by surgical shock, was the true reason for the insanities which follow operations on these organs.

Dr. G. H. Kirby said that at the Manhattan State Hospital and in the service of the Pathological Institute he had recently had eight cases in which the psychoses seemed to be more or less directly connected with operations on the generative organs. In four cases he was not able to determine whether the ovaries had been removed; in the other four cases they had undoubtedly been removed. Two were cases of excitement resembling mania; one of these patients recovered, the other patient was discharged improved; the third one was a case of dementia præcox, and in the fourth patient the symptoms were those of an agitated melancholia of the involution period. The general conclusion was that there was no special type of psychosis following such operations. His experience in general coincided with what Dr. Hammond had said.

Dr. Adolf Meyer stated that in the main the statements of Dr. Hammond seemed to coincide with the experience just mentioned. There would hardly be so much objection to drawing a parallel between the loss of the ovaries by operation and the loss of function during the involution period, so far as his experience with the anatomical condition of the ovaries after involution had taken place would make him think, but for argument no doubt Dr. Hammond was right in eliminating that point, because it would be difficult to convince the opponent. He doubted whether it were wise to say that only hereditary or congenital conditions would allow the formation of psychoses, since it seemed fairly probable that individuals with a fair start in life could, nevertheless, in the process of development undergo such constitutional changes as to expose them to mental breakdowns. A large number of cases that finally consented to gynecological operations, and that came under discussion in this topic, were, however, individuals who had a strongly disorganized mental makeup, further aggravated by the points which Dr. Hammond had so well described. Replying to Dr. Hammond's question whether psychoses had been observed following other operations, Dr. Meyer said that occasionally psychoses were attributed to other operations, but there again we had the same thing. As a rule the nature of the psychosis corresponded to the constitutional makeup of the individual, or such matters as the exhaustion, shock, infection, etc., which occurred in the post-operative condition.

Dr. Maurice C. Ashley agreed with what Dr. Hammond had said, and stated that in his experience with such cases, which had not been great, he had seen a number of cases of insanity which had been attributed to operations upon the reproductive organs, and all observers had seen many such operations where no psychosis followed. Psychoses had also been attributed to some profound mental shock, such as the loss of friends or financial reverses, but other similar shocks and losses were frequently noted in which no phychosis followed. Why, then, should any persons sustaining similar shocks, or submitting to like operations, develop a psychosis unless there were some inherent weakness or predisposition to insanity in those who did become insane? It seemed impossible to say definitely that the psychosis in any given case was the result of an operation.

Dr. L. Pierce Clark said that while his experience had been limited in observation of these cases it coincided with Dr. Hammond's views expressed in the paper of the evening. The occurrence of insanity after such operation seemed to him to argue for a primary constitutional defect, a marked predisposition. The exhaustion, fatigue, and worry leading to such operation, while considerable in degree, could not be regarded in any other light than as inciting factors to insanity.

Dr. Carlos F. Macdonald coincided with the position taken by Dr. Hammond with reference to the etiological importance of heredity in these cases. He was disposed to attach more and more importance to heredity as a causative factor in all forms of insanity. He thought it was rarely the case that a surgical operation of so serious a nature as oophorectomy produced insanity except in individuals who had an unstable mental and nervous organization, whether inherited or acquired. As a matter of fact, it was exceptional for insanity to follow surgical operations, or severe injuries of any kind, even injuries to the head, although it was a common idea, even among the profession, that injuries to the head frequently resulted in mental disease. In determining the cause of the disease in a given case we were too much in the habit of seeking for some event or incident in the life of the individual, some injury or disease outside the brain, and to regard that as the cause of the mental disorder. For himself, he had come to attach less and less importance to the so-called exciting causes of insanity and to look for the predisposing causes

Alcohol, for example, rarely produced insanity except in persons who were congenitally or otherwise predisposed thereto. In paresis, also, writers attached far too much etiological importance to excesses, particularly sexual excesses, when, as a matter of fact, many individuals were given to excesses of that kind who never succumbed to mental disease. As Dr. Hammond had well said, there must be a predisposition to the disease before these so-called exciting causes could become operative. A few years ago it was a popular fad with gynecologists to remove the ovaries for the cure of insanity. That idea was practically exploded now among alienists. He had had under his care for ten years a woman, fifty-eight years of age, who about fifteen years ago had her ovaries removed. The operation not only failed to cure her of her insanity, but she was markedly erotic, notwithstanding the removal of her ovaries and the fact that she had passed the usual age of the climacteric. The only way in which what we were accustomed to call the exciting causes of insanity could become operative was by undermining the general health and thus bringing about a condition of malnutrition of the brain, and thereby predisposing the individual to a true psychosis. This would apply to surgical operations as well as to other exciting causes.

Dr. William Hirsch said that in the subject which Dr. Hammond had discussed there were several points on which he thought every psychiatrist ought to take a decided stand. It was not long ago that just the opposite standpoint was taken by all gynecologists, and he did not agree with Dr. MacDonald, that this view was entirely exploded. He encountered a great many cases in which the question of removal of the ovaries came up without any local reason whatever. Eight years ago he had under his care a young woman who had at the time an acute psychosis. During her illness quite a number of consultations took place, and besides others the patient was seen by the most prominent gynecologists of that time. He positively insisted upon the removal of the ovaries. They were not diseased, but he insisted on curing the psychosis by removing the ovaries, and cited many cases of a similar kind. The speaker was utterly opposed to the operation, which, therefore, was not done. In the meantime the woman lost a child, which would undoubtedly have had a lasting effect on her mind if she could not have become pregnant again, which she did after a few years. She was now perfectly well. The speaker said he was entirely convinced that if the ovaries had been removed she would not have recovered from her mental trouble. Another point of importance was the question whether the removal of the ovaries had a specific effect on the mental condition as did the removal of the thyroid gland. This was a question which could not be decided theoretically, but merely by practical experience, and he did not think that anybody could say that his clinical experience justified any such assumption. After complete removal of the thyroid gland we were bound to expect certain symptoms, while we knew that no special symptoms necessarily followed the removal of the ovaries. Therefore he did not think the ovaries had any physiological function except the sexual function. For this reason the removal of the ovaries could not produce insanity any more than any other operation. The speaker fully coincided with those who held that view, except, perhaps, for those psychical reasons which Dr. Hammond mentioned. Of course the shock and the morbid ideas connected with this operation might be much greater than those of any other operation, but the psychosis itself would be the same as any other post-operative psychosis, which was exactly the same as a traumatic psychosis. There was such a thing as traumatic psychosis. He personally held that a traumatic psychosis was clinically well marked and could be diagnosed merely from its clinical symptoms. These cases were not seen in institutions, and were more frequent in private practice, for the reason that the true traumatic psychoses ran a very short course. He had seen a number of these cases which passed into wild delirium, connected with hallucinations, interrupted by lucid intervals, and lasting altogether only a few weeks at the utmost. The third point was the question whether any normal individual, with a perfectly normal mind, could ever acquire a post-operative psychosis, or whether it required a predisposition, such as congenital malformation of the psychical organ or constitutional inferiority. Dr. Hirsch fully agreed with all the speakers that a perfectly normal brain could not acquire a psychosis after any operation, unless it were an organic trauma to the brain. From mere shock from an operation in any part remote from the brain no mental disease would develop, unless there were such a predisposition. He did not quite agree with Dr. Hammond in putting paranoia with those diseases which could be acquired by a trauma. A normal man could never become a paranoiac. Paranoia was an exquisitely degenerative disease; that is, the mind of a paranoiac never was a normal one, even if the paranoia did not manifest itself as such in earlier life.

Dr. E. A. Macdonald said that he could not add anything to what the other gentlemen had said, and with which he entirely agreed. His own experience in hospital superintendency had not brought to notice a great many cases of insanity caused by operations upon the uterus and its appendages, this being partly, no doubt, due to the fact that in the main he had been connected with hospitals where only male patients were treated. Dr. Carlos Macdonald had anticipated him in referring to the much more frequent claim that *sanity* follows such operations in the case of the *insane*. He did not quite believe with Dr. Macdonald that such claims of the gynecologists, as he suggested, were at an end, though they were by no means so common as they were a few years ago. A number of years ago—as Dr. Hamilton would remember, because he was then editor of a journal that took particular notice of the claim—a distinguished gynecologist came to New York and made the statement publicly that at least 85 per cent. of insanity in women was distinctly traceable to disease of the uterus and appendages, and that cure was to be found in operation upon these organs. Dr. Hamilton would also recall some cases in which without special symptoms the cause of insanity was attributed to the ovaries and operation was performed, perfectly healthy ovaries being removed. In one particular case this was done in spite of his and the speaker's protest. What the effect of the operation upon the insanity might have been he could not say, because the patient died under the operation. Since that time he had seen no reason to alter his opinion that operations upon the uterus or the ovaries had very little specific importance in the production of insanity. In the few cases which he had seen of insanity following such operations he thought it was not due to the particular operation, but to the after-effects—shock, exhaustion, etc.—incident to any surgical procedure.

Dr. Allan McLane Hamilton said that his experience had been considerable, and he knew of many cases where, in the face of the objections of himself and others, oophorectomy had been performed. For the most part these patients presented symptoms that in no way could be connected with the ovaries or pelvic organs, and he recalled even one alcoholic dement who was spayed. He remembered very well the cases referred to by Dr. A. E. Macdonald, and the agitation at the time when for a considerable period the gynecologist was consulted to the exclusion of the psychiatrist. The case related by the doctor was one of catalepsy, and, despite the operation, the patient not only showed no return to ordinary consciousness, but died in a few days thereafter from the effects of the operation. He wrote a paper at the time and cited some examples which clearly proved that no benefit followed the removal of the ovaries, but actual harm was instead done. In some examples of the psychosis which was now known as precocious dementia, which was occasionally recoverable, this pernicious interference had a lamentable effect, and the psychic shock was always a disastrous element. In but one

case had the speaker seen good results from the suggestion of an operation of this kind, and this was in a neurasthenic with insistent ideas. The fear of the surgeons really aroused or cured the young woman. Dr. Hamilton said we had a duty to perform, and that was to educate, or at least caution those daring members of our profession who not only wrongly connected neuroses and actual organic disease, but psychoses as well with various bodily ailments and defects. It was not so long ago that epilepsy, and even tabes, were cured (?) by section of the ocular muscles, and Erb's spastic paralysis was cured by circumcision. There seemed to be a great deal of ignorance about the somatic causation of insanity, and this had led to errors not only in diagnosis, but treatment as well.

Dr. Hammond, in closing the discussion, agreed with Dr. Hirsch's remarks concerning paranoia, saying he did not mean to imply that operation on the ovaries could cause paranoia, but that there are many cases in which paranoiac symptoms are dormant until after operation on the pelvic organs, when such symptoms become very prominent.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundredth Annual Meeting, Held in Albany, January 30, 31, and February 1, 1906.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 202.*)

THE PRESIDENT, DR. JOSEPH D. BRYANT OF NEW YORK, IN THE CHAIR.

THURSDAY, FEBRUARY 1—THIRD DAY.

Clinical Notes on Exophthalmic Goiter.—Dr. W. GILMAN THOMPSON of New York read this paper, which was based upon a study of upwards of 40 collected cases, including several treated with Dr. Rogers' cytotoxic serum. The object of the research was to emphasize the importance of certain symptoms which pointed conclusively to the toxic rather than the purely neurotic character of the disease. In almost all serious cases, and in probably all fatal cases, there were definite febrile exacerbations, accompanied by acute dilatation of the heart, the development of murmurs, intense precordial distress, often gastric or other abdominal pain, attacks of vomiting and diarrhea, active perspiration, sensations of suffocation, insomnia and great restlessness, an erythematous rash, and edema of the feet and legs. Such a symptom group pointed clearly to the influence of a toxemia due to hyperthyroidism. The effect of the Rogers cytotoxic serum was to inhibit the hyperthyroidism. This serum was prepared 'from the diseased human thyroid gland, which was extracted and passed through living rabbit's blood. The resulting serum was found to contain both a cytotoxin and an antitoxin. Dr. Thompson had seen several of the cases treated by Dr. Rogers with the serum, in which remarkable and rapid improvement had resulted—in two of the writer's cases after all hope of recovery through ordinary means of treatment had been abandoned. Dr. Thompson further advanced the view that in many cases the agent which excited the acute exacerbations met with in exophthalmic goiter was to be found in some simple intercurrent infection, such as an attack of bronchitis, pharyngitis, or very often acute tonsilitis. One or other of these infections was observed in 16 out of 43 cases of Graves' disease at the onset of serious acute exacerbations.

Simplified Method of Testing for Blood in Feces.—Dr. A. L. BENEDICT of Buffalo said that Boas had applied to feces the ordinary guaiac test for hemoglobin, which could not be applied to feces directly, as the consistency and opacity of the fecal mass obscured the characteristic blue color. The essential point in the Boas test was the preparation of the clear extract of blood pigment by means of acetic acid and ether and, as the ether would also dissolve out the fats, a preliminary extract of fats was made with ether alone. These two extractions, while not especially troublesome in a well-equipped laboratory, were somewhat tedious and disagreeable, as the contents of the test tube were liable to spurt. After various trials of all sorts of extracting agents and checking the results with the regular Boas test, the writer devised the following, the use of gasoline being suggested by his previous modification of the indican test in urine, gasoline having been found to extract indigo better than chloroform did. About two c.c. of liquid, or one c.c. of solid feces, was taken, diluted, and shaken with water, if necessary, to reduce it to the consistency of diarrheal discharge. Either a test tube or bottle might be used. A given quantity of gasoline was added. A little freshly whittled gum guaiac dissolved in about one c.c. of grain or wood alcohol, was added, and then a few drops of ozonized (c.p.) oil of turpentine. While fats were, to some degree, extracted by the gasoline, they did not interfere with the test and, if blood was present in detectable amounts, the gasoline assumed a distinct bluish tinge. The gasoline had the practical advantage of deodorizing. As no elaborate apparatus was needed and any clear glass bottle could be used, the test could conveniently be applied at the patient's residence and small vials of fresh tincture of guaiac and turpentine could be carried in the pocket, if desired.

The Somatic Evidences of Syphilis in Paretics.—Dr. JAMES M. WINFIELD of Brooklyn read this paper by title, reporting the results of examinations for the external evidences of syphilis among 241 patients in six of the New York State Hospitals for the Insane. The doctor found that nearly 75 per cent. of those examined showed the various signs and stigmata of cutaneous syphilis. In the individual hospitals the largest percentage was found in those of the rural districts and the one for the criminal insane. From his findings the doctor concluded that syphilis was a very important factor in the production of general paralysis of the insane.

An Inconsistent Feature of the Oath as at Present Administered.—Dr. WILLIAM BROWNING of Brooklyn said that as medical men were probably called upon more often than any other class to give testimony, they had an ample warrant for considering forms of procedures. It was to the second portion of the oath, referring to the "whole truth," that attention was directed. It was a common criticism that frequently the witness was not permitted to fulfill this. It could be corrected by some simple modification of the present wording.

Diaphragmatic Grooves on the Liver.—Robert Orton Moody writes that grooves on the convex surface of the liver have been more or less carefully studied since the close of the sixteenth century. There has been much discussion concerning the etiology of these grooves which has resulted in the development of various theories. Although, as the writer states, it is evident that study of this subject so far can yield no theoretical generalizations, nevertheless it suggests some new possible causes in certain cases and presents some interesting evidence which modifies previous interpretations. From his careful researches, Moody presents the following conclusions: Diaphragmatic grooves are found in the fetus as early as seven months, in infancy, in youth, and in old age. The grooves may or may not contain folds of the diaphragm; the latter are sometimes permanent and sometimes disappear when the liver and diaphragm are removed from the body. The comparatively small number of cases recorded does not justify definite generalizations concerning the frequency of these grooves and the age and sex of subjects in which they are most often found. Many factors take part in the production of the grooves, some of which may be congenital conditions of the diaphragm, difficult respiration, constriction of the thorax and abdomen by clothing, severe diaphragmatic pleurisy, localized peritonitis, and a disproportionate ratio between the size of the liver and of the abdominal cavity.—*Bulletin of the Johns Hopkins Hospital.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE FOOD FACTOR IN DISEASE. In two volumes, by FRANCIS HARE, M.D. 8vo, 1,032 pages, illustrated, muslin. Longmans, Green & Co., New York. Cloth, $10.00, net.

MILITARY HYGIENE. By ROBERT CALDWELL, F.R.C.S. 8vo, 416 pages, illustrated, muslin. Wm. Wood & Co., New York. Cloth, $4.00, net.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS. Twentieth Session. 8vo, 546 pages, illustrated, muslin.

A COMPEND OF MEDICAL CHEMISTRY, INORGANIC AND ORGANIC, INCLUDING URINARY ANALYSIS. By HENRY LEFFMANN, M.D. Fifth Edition, revised. 16mo, 200 pages, illustrated. P. Blakiston's Son & Co., Philadelphia.

PHARMACOLOGY AND THERAPEUTICS. By REYNOLD WEBB WILCOX, M.A., M.D., LL.D. Sixth Edition, 8vo, 1,010 pages, muslin. P. Blakiston's Son & Co., Philadelphia.

MASSAGE AND THE SWEDISH MOVEMENTS. By KURRE W. OSTROM. Sixth Edition, 12mo. 184 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia.

MAN AND HIS POISONS. By ALBERT ABRAMS, A.M., M.D. 8vo, 268 pages, illustrated, muslin. Price, $1.50. E. B. Treat & Co., New York.

THE MANAGEMENT OF A NERVE PATIENT. By DR. ALFRED T. SCHOFIELD. 12mo, 267 pages, muslin. P. Blakiston's Son & Co., Philadelphia.

THIRTY-FIFTH ANNUAL REPORT OF THE SECRETARY OF STATE ON THE REGISTRATION OF BIRTHS AND DEATHS, MARRIAGES AND DIVORCES IN MICHIGAN FOR THE YEAR 1901. By FRED M. WARNER, Secretary of State. Edited by Cressy L. Wilbur, M.D. 8vo, 117 pages, muslin. Robert Smith Printing Company, Lansing, Mich.

REFRACTION, INCLUDING MUSCLE IMBALANCE AND THE ADJUSTMENT OF GLASSES. By ROYAL S. COPELAND, A.M., M.D., and ADOLPH E. IBERSHOFF, M.D. 8vo, 144 pages, illustrated, muslin. Price, $1.50, net. Boericke & Tafel, Philadelphia.

SURGICAL NURSING AND THE PRINCIPLES OF SURGERY FOR NURSES. By RUSSELL HOWARD, M.B., M.S., F.R.C.S. 12mo, 318 pages, illustrated, muslin. Edward Arnold, London, England. Price, $1.70, net.

QUIZ-COMPENDS, A COMPEND OF DISEASES OF THE SKIN. By JAY F. SCHAMBERG, A.B., M.D. Fourth Edition. 12mo, 209 pages, illustrated, flexible muslin. P. Blakiston's Son & Co., Philadelphia.

URINARY ANALYSIS AND DIAGNOSIS BY MICROSCOPICAL AND CHEMICAL EXAMINATION. By LOUIS HEITZMANN, M.D. Second Edition. 8vo, 319 pages, illustrated, muslin. Price, $2.50, net. William Wood & Co., New York.

A TEXT-BOOK OF PHARMACOLOGY AND THERAPEUTICS OR THE ACTION OF DRUGS IN HEALTH AND DISEASE. By ARTHUR R. CUSHNY, M.A., M.D. Fourth Edition. 8vo, 752 pages, illustrated, muslin. Price, $3.75, net. Lea Brothers & Co., Philadelphia.

THE STRANGE STORY OF THE QUILLMORES. By A. L. CHATTERTON. 12mo, 272 pages, illustrated, muslin. Stitt Publishing Company, New York.

A MANUAL OF MATERIA MEDICA AND PHARMACOLOGY. By DAVID M. R. CULBRETH, Ph.G., M.D. Fourth Edition. 8vo, 976 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia.

FOOD AND DIET IN HEALTH AND DISEASE. By ROBERT F WILLIAMS, M.A., M.D. 12mo, 392 pages, muslin. Price, $2.00, net. Lea Brothers & Co., Philadelphia.

A MANUAL OF BACTERIOLOGY. By HERBERT U. WILLIAMS, M.D., revised by B. Meade Bolton, M.D. Fourth Edition 8vo, 357 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia.

THE PATHOLOGY OF THE EYE. By J. HERBERT PARSONS B.S., D.Sc., F.R.C.S. Volume 2, Histology, part 2. 8vo 770 pages, illustrated, muslin. G. P. Putnam's Sons, New York.

THE ANIMAL PARASITES OF MAN. By Dr. MAX BRAUN. Translated by Pauline Falcke. Third Edition. 8vo, 453 pages, illustrated, muslin. William Wood & Company, New York. Price $5.00 net.

A TEXT BOOK OF PSYCHIATRY FOR PHYSICIANS AND SURGEONS. By LEONARDO BIANCHI, M.D., JAMES H. MACDONALD, M.B., Ch.B. Glasg. 8vo, 904 pages, illustrated. muslin William Wood & Company, New York. Price $6.00 net.

THE TEACHERS' PART IN THE TUBERCULOSIS PROBLEM.*

BY S. A. KNOPF, M.D.,

NEW YORK.

ASSOCIATE DIRECTOR OF THE CLINIC FOR PULMONARY DISEASES OF THE HEALTH DEPARTMENT; VISITING PHYSICIAN TO THE RIVERSIDE SANATORIUM OF THE CITY OF NEW YORK; CONSULTING PHYSICIAN TO THE SANATORIA AT GABRIELS, N. Y., SCRANTON, PA., BINGHAMTON, N. Y., ETC.

MR. CHAIRMAN, LADIES, AND GENTLEMEN:—

As a director of the National Association for the Study and Prevention of Tuberculosis and as a member of the Tuberculosis Committee of the Charity Organization Society, I desire, in the name of our association and of the committee, to express my deep appreciation of the valuable cooperation which the Board of Education of the City of New York has given us by inviting its 14,000 school teachers to visit our tuberculosis exhibition. Personally I desire to express my most heartfelt thanks to my colleagues on the board of directors and the committee for the honor they have conferred upon me by selecting me as the speaker this evening.

It is indeed a privilege to address the teachers of a great city like this—the educators of the men and women of the coming generation. That you have come out in such large numbers is evidence of what a high conception you have of your own calling, for in addition to the many duties you have to perform, you have come here to hear me discuss a subject which is not pleasant, and perhaps not even interesting. But, in your labors as teachers as well as in ours as physicians, we must often deal with subjects which are neither pleasant nor interesting. A sense of duty alone helps us to accomplish such tasks.

The subject assigned to me to-night is "The Teachers' Part in the Tuberculosis Problem." In order that you may perform your part in the campaign against this common foe, which, on account of its prevalence and great mortality it causes, has very justly been called by the immortal Oliver Wendell Holmes "the great white plague." It is above all necessary that you should know something of the nature of the disease which we seek your cooperation to combat.

As teachers you should know even something of the history of the disease. Pulmonary tuberculosis, phthisis pulmonalis, or consumption, was well known to many of the ancient physicians, and it may be a surprise to some of you to learn that Hippocrates, the most celebrated physician of antiquity, who lived from 460 to 377 B. C., and who may be truly called the father of scientific medicine, described consumption as a disease which is "the most difficult to treat, and which proves fatal to the greatest number of people." Isocrates, also a Greek physician, who lived about the fifth century before Christ, was the first to write of tuberculosis as a disease transmissible through contagion. In the middle ages (1550) the celebrated physician, Montano, declared consumption to be one of the most dangerously contagious and most easily contracted of diseases. An equally strong advocate of the theory of contagion was the celebrated anatomist, Morgagni (1682-1771), who never performed an autopsy on an individual who had died from tuberculosis. In Naples a royal decree, dated September 20, 1782, ordered the isolation of consumptives and the disinfection of their apartments, personal effects, furniture, books, etc., by means of vinegar, brandy, or lemon juice, seawater or fumigation. Any violation of this law was punished, if the individual was an ordinary mortal, by three years in the galleys, and if he happened to be a nobleman he was sent for the same length of time to the fortress and had to pay a fine of 300 ducats. The physician who failed to notify the authorities of the existence of a tuberculous patient was fined 300 ducats for the first offense, and a repetition of the neglect would banish him from the country for ten years.

In the first half of the nineteenth century little attention was paid to the theory of infectiousness of tuberculosis even by medical men. The contagiousness or communicability of the disease could not be scientifically demonstrated, and although there were physicians here and there who believed in the infectiousness of the disease, nothing positive was taught in regard to it at the centers of medical learning. A last, in 1865, the French physician, Villamin, demonstrated beyond a doubt that tuberculosis could be transmitted from one individual to another. He inoculated animals with tuberculous substances and reproduced tuberculosis not only in the lungs, but also in other portions of the body.

After this discovery there seemed to be no longer a doubt that tuberculosis was an infectious disease and that for its production a specific germ was essential. The discovery of this specific organism (Bacillus tuberculosis) was reserved to the great German scientist, Robert Koch (1882).

How very prevalent this disease is is known to most of you, and I will not detain you with detailed statistics, but simply state that each year the world yields up 1,095,000, each day 3,000, each minute two of its people, as a sacrifice to this plague. Of the 80,000,000 individuals now peopling the United States more than 10,000,000 must inevitably die of this disease if the present ratio is kept up. According to some statisticians, every seventh, and according to others, every sixth death is due to tuberculosis.

On account of the fearful prevalence of this disease the Germans very appropriately have called consumption "eine Volkskrankheit"—a disease of the masses. And yet, in the light of modern science, we as physicians must acknowledge consumption,

*Address delivered before the teachers of the public schools of the City of New York at the American Tuberculosis Exhibition, held in the American Museum of Natural History, under the auspices of the National Association for the Study and Prevention of Tuberculosis and the Committee on Tuberculosis of the Charity Organization Society, December 8, 1905; revised for publication in the MEDICAL RECORD, February 3, 1906.

although the most prevalent of all infectious and communicable diseases, to be nevertheless the most curable and most preventable of them all.

The disease is chronic, which means that it lasts long; it is communicable, which means that it can be transmitted from man to man, from man to beast and from beast to man. It is preventable, which means that it is in the power of man to stop its propagation. It is curable, because by judicious treatment the majority of patients can be cured, particularly in the early stages.

What are the characteristics of this complex disease? It is caused by the presence of the tubercle bacillus, or germ of consumption in the lungs. It is locally characterized by countless tubercles, that is to say, small rounded bodies, visible to the naked eye. The bacillus of tuberculosis is a minute organism, in the shape of a cylindrical rod, visible with a high-power microscope only after certain staining reagents have been applied to it. This microorganism, belonging to the order of schizomycetes or fission-fungi in the lowest scale of vegetable life, is the specific microbe of consumption; without its presence there is no tuberculosis. This parasite not only gradually destroys the lung substance through ulcerative processes, but at the same time gives off certain poisonous substances called toxins which give rise to various, and often serious, symptoms.

The important symptoms of pulmonary tuberculosis are cough, expectoration, fever—especially in the evening hours—difficulty in breathing, pains in the chest, night-sweats, loss of appetite, hemorrhages, and emaciation. The tubercle bacillus is found in the matter expectorated.

How may this germ of consumption enter the human system?

There are really three methods whereby this germ may enter, namely, by inhalation, that is, being breathed into the lungs; by ingestion, that is, being eaten with tuberculous food; and by inoculation, that is, the penetration of tuberculous substance through a wound in the skin. Let us speak first of the most frequent method of the propagation of tuberculosis, namely, that arising from the indiscriminate deposit of tuberculous sputum. A consumptive individual, even at a period when he is not confined to his bed, may expectorate enormous quantities of bacilli. By careful observers it has been estimated to amount in some individuals to about 7,000,000,000 per day. Now, if the expectoration, or spittle, is carelessly deposited here and there, so that it has an opportunity to dry and become pulverized, the least draft or motion in the air may cause it to mingle with the dust, and the individual inhaling this dust-laden atmosphere is certainly exposed to the danger of becoming tuberculous if his system offers a favorable soil for the growth of the bacilli. By "favorable soil for the growth of the bacilli" must be understood any condition in which the body is temporarily or perpermanently enfeebled. Such a condition may be inherited from parents, or acquired through alcoholism or drunkenness, or other intemperate habits, through privation or disease.

Besides the danger arising from carelessly deposited sputum, or spittle, the inhalation or ingestion of the small particles of saliva which may be expelled by the consumptive during his so-called dry cough, when speaking quickly or loudly, or when sneezing, must also be considered as dangerous for those who come in close contact with the invalid. These almost invisible drops of saliva may contain tubercle bacilli. Recent experiments in this direction have shown the possibility of infection by this means.

The next most frequent method of the propagation of tuberculosis is through the ingestion of the bacilli, that is to say, when the germ of consumption is taken with the food.

The third and much less frequent cause of tuberculosis is inoculation, or penetration of the tuberculous substance through the skin.

What should we do to stop the first and most frequent source of the dissemination of the bacillus?

A patient suffering from pulmonary consumption should know that, no matter in what stage of the disease he may be, his expectoration, or spittle, may spread the germ if the matter expectorated is not rendered innocuous before it has a chance to dry and become pulverized. The patient should, therefore, always spit in some receptacle intended for that purpose. It is best to have this vessel made of metal so it will not break. It should be half filled with water or some disinfecting fluid, the main thing being to make it impossible for the expectoration to dry.

In schools, factories, stores, railroad cars, waiting rooms, court rooms, restaurants, saloons, meeting places, theaters, menageries—in short, wherever many people congregate—there should be a sufficient number of cuspidors well kept and regularly cleaned. They should be made of unbreakable material and have wide openings. If such measures are carried out, there will be no excuse for anyone to expectorate on the floor and thus endanger the health of his fellowmen.

When out of doors the patient should use a pocket-flask of metal, strong glass, or pasteboard. There are numerous kinds of flasks for this purpose in the market.

A handkerchief should never be used as a receptacle for sputum. Patients who are too sick to make use of light porcelain or aluminum cups should have a number of moist rags within easy reach. Care should be taken that the rags always remain moist, and that the used ones are burned before they have a chance to dry. The paper spit-cups with their contents should, of course, also be destroyed by fire.

There will always be some consumptives who cannot be persuaded to use the pocket-flask, for the reason that they do not wish to draw attention to their malady. The only thing for such people to do is to use squares of soft muslin, cheese cloth, cheap handkerchiefs, or Japanese paper handkerchiefs specially manufactured for that purpose, which can be burned after use. They should place in their pockets a removable lining of rubber or other impermeable substance which can be thoroughly cleaned. This additional pocket could be fastened to the inside of the ordinary pocket by clamps, and would thus be of no inconvenience to the patient. A pouch of vulcanized rubber or an oriental tobacco pouch may be used in place of the extra pocket of impermeable material.

The danger of dissemination of the bacilli through the so-called dry cough is relatively small; we should, nevertheless, insist that the patient holds a handkerchief before his mouth and nose when he coughs or sneezes. The consumptive should be advised to carry two handkerchiefs with him, one to hold before his mouth and to wipe it with after having expectorated, the other to use only to wipe his nose. By being careful with the use of his handkerchiefs, the danger of infecting his nose and bronchial tubes will be materially lessened.

All soiled linen (sheets, pillow cases, underwear, napkins, handkerchiefs, etc.) used by the consumptive should not be handled more than necessary, but should be placed in water as soon as possible after

removal from bed or body. It is better to wash these articles separately, and only after having been thoroughly boiled should they be put with the common laundry. Wherever it is not possible to carry out these precautionary measures in their entirety one should strive to follow them as far as it is in one's power.

Concerning the danger from infection through tuberculous food, we will say that whenever one is not reasonably certain that the meat he eats has been carefully inspected and is free from disease germs, it should be thoroughly cooked. By this means one is certain to kill all the dangerous microorganisms. Against the sale of tuberculous milk there are very excellent laws in some States of the Union which are rigorously enforced. In some the laws are less good, and in some there are no laws at the present time.

In justice to farmers and dairymen, it must, however, be said that there are many who do their very best to protect themselves and their fellowmen from the danger of tuberculosis. They have their cows tested regularly, destroy the animals which are found to be tuberculous, and keep their stables and utensils for milk as clean as possible.

Unless one can be reasonably sure that the cows from which the milk is derived are healthy, the milk should be boiled or sterilized before use, especially when it is intended as food for children. Milk obtained from stores and from milk peddlers should invariably be submitted to boiling or sterilization. When milk is kept slowly boiling for five minutes all the bacilli are killed, and the same result is obtained by the sterilizing process which is to keep the milk heated for at least half an hour at a temperature of about 70° C. or 160° F. There are now in the market a number of cheap and practical apparatuses for sterilizing milk, which can be obtained in almost any drug store.

Raw fruit bought from the pushcart man, or, for that matter, derived from any other source, should be washed, peeled, or cooked before being eaten. You teachers should impress these precautions upon the little ones and the big ones in your charge. If simple warning does not suffice, tell the children how some of the enterprising pushcart men treat an apple, for example, to make it shine and seem appetizing.

There is another way whereby the germs of consumption may possibly enter our stomach or intestines, namely, through kissing a consumptive or using utensils which have been soiled by the saliva of the patient. Therefore, the consumptive should never kiss, no matter whom, on the mouth, and children should be taught to allow no one to kiss them, except on the cheek, or not to be kissed at all.

Tuberculous patients should have their own drinking glasses, spoons, forks, etc., or, at least, all table utensils which have served for them should be placed in boiling water after use.

It is, of course, also possible for the consumptive to contract intestinal tuberculosis when, out of false modesty, he swallows his expectoration. May I be permitted to insert here a little medical advice? Unless the patient feels that he must expectorate, he should not cough. Dry coughing is scratching the throat because it tickles. This is not only impolite and unpleasant, but it also injures the patient's throat. With the exercise of a little will power and discipline one can suppress this dry and unnecessary cough. The consumptive patient should remember never to touch food before having washed his hands very thoroughly. Even with the greatest care it is possible that he may have soiled his hands with tuberculous expectoration.

Inoculation, or the penetration of tuberculous substance through the skin happens, perhaps, most frequently through injuries received while cleaning nicked or chipped glass or porcelain cuspidors which have been used by consumptives. It is also possible for the bacilli to enter the circulation if the person cleaning the spittoon happens to have a wound or open sore on his hands. Persons entrusted with the care of the spittoons in a private sick-room or an institution for consumptives should wear rubber gloves while cleaning these vessels.

At times the patient may inoculate himself by placing an accidentally injured finger in his mouth, or by carelessly soiling an open wound with his expectoration. If one has been unfortunate enough to receive an injury and tuberculous inoculation is feared, the best thing to do is to let the wound bleed freely, wash it thoroughly with water that has been boiled, with a five per cent. solution of carbolic acid, or with pure alcohol; dress the wound with a clean rag that has been dipped in any of these liquids, and seek as soon as possible the advice of the physician. This is a good thing to remember when the little ones under your charge come to you with injured fingers from no matter what source. By such precautionary measures you are almost certain to avoid serious wound infection.

I have thus far spoken only of that type of tuberculosis which manifests itself in the pulmonary form, that is to say, consumption of the lungs, of intestinal tuberculosis, or consumption of the bowels, and tuberculosis of the skin, or lupus. But you must know that every organ in the body, such as the throat, the bones, and the coverings of the brain and spinal column, is not infrequently invaded by the tubercle bacillus. In the last mentioned form the disease is technically called tuberculous meningitis.

After all you that have heard so far of the contagiousness, or, rather, the communicability of tuberculosis, and consumption in particular, I do not wish you to think that a breath accidentally taken in an atmosphere laden with bacilli would certainly render a healthy individual consumptive, or that by a swallow of tuberculous milk, or a little injury from a broken cuspidor one must necessarily become tuberculous. The secretions of our nasal cavities, doubtlessly also the blood, and the secretions of the stomach of the healthy individual, have bactericidal properties; that is to say, they kill the dangerous germs before they have a chance to do harm. Therefore, healthy men and women should not have an exaggerated fear of tuberculosis, but should, nevertheless, not recklessly expose themselves to the danger of infection.

Who are the individuals who must be particularly careful so as not to be attacked by the almost ever present tubercle bacillus?

There are four classes of these persons. First, those who have a hereditary predisposition to consumption; secondly, those who have weakened their system and thus predisposed themselves to the disease by the intemperate use of alcoholic beverages, by a dissipated life, by excesses of all kinds, etc.; thirdly, those whose constitution has been weakened by disease—pneumonia, typhoid fever, smallpox, measles, whooping-cough, syphilis, influenza, etc.; fourthly, those whose occupations, trades, or professions, such as printing, hat-making, tailoring, weaving, and all occupations wherein the worker is much exposed to inhalation of various kinds of dust, render them particularly liable to consumption.

Before I proceed to give you a few essential points showing how to overcome such a predisposition to

consumption, let me answer the question which is probably in the minds of many of you, namely, "What about those who have a so-called hereditary consumption?" Permit me to say that the popular notion concerning hereditary consumption is, in my humble opinion, absolutely erroneous. Consumption has, perhaps, never been inherited either from the father or the mother, but the child has usually been infected by its well-meaning but ignorant consumptive parents after birth. The mother has kissed the child, taken it into her bed, allowed it to use the same spoon or other utensils which she has used herself, and thus unconsciously has conveyed the disease to her infant.

The need of insisting on the possibility of infection through utensils was once impressed upon me so pathetically and vividly that I shall never forget the incident. I was honored by being called in consultation by a venerable physician, many years my senior, to see a young woman in presumably the earlier stages of consumption. On our way to the house of the patient my venerable colleague told me how careful he had been to instruct the woman of the nature of the disease, and that he had particularly forbidden her to kiss her child. Arrived at our destination I found the patient just giving her baby its lunch. In presenting her beautiful child to me she said, with tears streaming down her cheeks, that ever since her good old doctor had told her that she had consumption she had not once kissed her darling baby. But while telling me this pathetic story she was tasting the mush to judge of its sweetness and temperature, putting the spoon alternately into her own and into her baby's mouth. She would not intrust the feeding of her little one to anybody else.

Through kissing and caressing a consumptive father the child may also be infected, or, again, the one or the other parent may have been careless with their expectoration, and may have soiled the floor where the child plays. It must be obvious to any thinking individual that if such uncleanly habits of the father or mother prevail, the child born healthy is not likely to remain healthy long.

I have said that consumption is not hereditary, and children born of consumptive but intelligent and conscientious parents need not necessarily contract the disease. I, myself, numbers of times have seen children of a consumptive parent grow up to be strong men and women; but their parents were not only careful, clean and conscientious; they were also aware that while they did not transmit consumption to their children, they had transmitted to them a tendency, or predisposition, to this disease. This hereditary predisposition is, however, a condition which can be overcome by judicious training, proper food, plenty of out-door exercise, and the avoidance of all excesses. Every predisposed individual should dress sensibly and according to the season. Never should they wear garments which restrict circulation or hinder the free physiological function of the chest or abdomen. Tight clothing, tight neckwear, tight shoes are all pernicious and particularly dangerous to the individual predisposed to tuberculosis.

I have already hinted at what should be the duty of the parents if they are themselves consumptive and fear to have transmitted to their offspring a predisposition to the disease. Concerning alcoholism, which is so often the forerunner of consumption, I desire to speak plainly. I do not wish to appear to you as a temperance lecturer, condemning all and everything which does not subscribe to the doctrines of the temperance party. I consider alcohol a medicine, at times indispensable in the treatment of certain diseases; but liquor as a beverage is never useful, and nearly always harmful. Alcoholism must be considered the greatest enemy of the welfare of a nation, the most frequent destroyer of family happiness, too often the cause of the ruin of mind and body, and certainly the most active cooperator of the deadly tubercle bacillus.

How to combat alcoholism is in itself a problem. I confess that to my mind the only rational way is to follow the example of Norway and some of the Cantons of Switzerland, by making the manufacture and the sale of alcohol a government affair. Experience in these countries has shown that through such means alone they have been able to reduce alcoholism and its consequent evils—disease, crime, poverty, misery, and want.

Educational propaganda regarding alcoholism will also be helpful. Concerning tuberculosis it should be impressed upon the masses that alcohol, in whatever form it may have been administered, has never been either a prevention or a cure for consumption. Since we have not yet any laws prohibiting the sale of patent preparations, containing a large percentage of alcohol under the guise of medicine, we must educate the people to the true state of affairs. It may surprise you to learn that most of the alcohol sold in this country is not sold over the bar as whiskey, but in the form of patent medicines, and of patent medicines the American people consume, according to the estimate of my venerable friend, Professor A. Jacobi of Columbia University, no less than $200,000,000 worth a year.

Complete analyses of 67 patent medicines have been made by the late Dr. Samuel W. Abbott of the State Board of Health of Massachusetts and published in his Report on Food and Drug Inspection for the year 1902. This list has appeared in an admirable article by Mr. Bok of the *Ladies' Home Journal*, and I must refer my readers who are interested in the subject to these publications.* They show that these 67 analyzed patent medicines, some of them advertised as entirely harmless, or as a cure for inebriety, contain from 6 to 44 per cent. of alcohol. Another article which I would advise teachers and family practitioners to peruse carefully, is the one by Samuel Hopkins Adams, in *Collier's Weekly* of October 28, 1905, entitled, "Peruna and the Bracers." To show the thoroughness of Mr. Adams' investigation, I will simply quote the titles of the subchapters of this contribution to the subject: "What Peruna Is Made Of"; "The Government Forbids the Sale of Peruna to Indians"; "Two Testimonials": "Medicine or Liquor?" "Some Alcoholic Percentages."

Other works, such as those of Professor Osborne of Yale, Dr. Ashbell P. Grinnell, Miss Allen, etc., should be studied by all who are interested in combating alcoholism and tuberculosis. They should be reprinted and receive the largest possible circulation, not only among the ignorant masses but also among the intellectual classes, our statesmen and our ecclesiastics. ' These latter will, perhaps, then refrain from endorsing patent medicines of the composition and effect of which they have not the slightest idea.

In families in which there is a fear of hereditary transmission of the desire for strong drink, even the mildest alcoholic drinks should be absolutely avoided. It would also be best if all people so predisposed, or who may have acquired only the occasional desire for drink, should never smoke, for experience has taught that attacks of dipsomania (periodical sprees)

* In an article entitled "The Family Physician as a Factor in the Solution of the Tuberculosis Problem," which appeared in the *Journal of the American Medical Association* of October 22, 1904, I reproduced the list just as it was sent to me by Dr. Abbott, on account of some inaccuracies which had occurred in other publications.

are often caused by an excessive use of tobacco. The young man starting out in life should take with him the moral training which will enable him to be a gentleman, and be considered a polite gentleman, though he absolutely refuses ever to enter a liquor saloon in order to treat or be treated to drink. It is this treating habit—alas! so prevalent in our American society, which has ruined many a young man and made him a moral and physical wreck. Think of it, ladies and gentlemen, you, the teachers of our boys and girls, what a glorious mission you have in thus combating two diseases of the masses—alcoholism and tuberculosis—at the same time. You are not only teachers, but citizens as well, and as such should encourage the creation of tea and coffee houses, where warm, non-alcoholic drinks, including bouillon, are sold in winter and cold ones in summer. It would be an additional advantage if some of these houses could also offer healthful amusements for old and young. Temperance societies, which through tactful and intelligent propaganda help to combat the fearful evil of alcoholism, should receive encouragement from everybody.

What I have said so far of the causes and prevention of tuberculosis is knowledge which, it seems to me, should be possessed by every person, but you teachers should be particularly posted on the minute details, so that you may not only practise them for your own self-protection, but also preach them, not only as teachers, but also as friends of all the unfortunate.

Thus, if you are perchance in the presence of a consumptive who is not yet under medical care, teach him what you know of the prevention of the disease and advise him to seek the counsel of a competent physician. If he is too poor to pay for a consultation, and too proud to ask it for nothing, tell him to apply to a tuberculosis dispensary or to the Health Department, which will send him one of its physicians without cost. No tuberculous invalid, no matter in what stage of the disease, whether living in a palace or in the poorest tenement house, should be without a medical adviser. If you meet a consumptive who is ignorant of the precautions he should take, do not shun him like a leper, but treat him with kindness and convince him that whatever he does to prevent the spread of the disease among others will also improve his own condition and increase the chances of his recovery. Let me tell you that a clean, conscientious consumptive is as safe a person to associate with as anybody.

Now, let me come to some of the particular duties devolving upon you as teachers in the combat of tuberculosis as a disease of the masses. You should teach and practise love for fresh air. Your pupils should learn to love fresh air as much as you do and take this love for fresh air home with them. Let me incidentally mention a place where tubercle bacilli abound and where you find at certain hours more children than even at school. I refer to our menageries. To visit the ape-house in the zoological gardens and to remain there as long as possible is the delight of children, and yet, perhaps next to cattle, there are no animals so subject to tuberculosis as apes, nearly 90 per cent. being afflicted with the disease. Add to this the commotion, dust, and impure air in the average ape-house at the usual time of the children's visits, and one cannot help thinking of an absolute danger. There seems no reason why an ape-house, containing numerous consumptive animals, should not be as much a source of infection as a tenement house, where ignorant and careless tuberculous individuals have expectorated indiscriminately.

There should always be ample ventilation in your classrooms. The vitiated atmosphere in the classroom is as pernicious to you as it is to the children under your charge. Keep your schoolroom windows open all the time when the weather is mild; when the weather is cold, open them for a few minutes every three-quarters of an hour, or hour, so as to assure an absolute change of air. No artificial ventilation, however perfect, can equal the direct access of pure, fresh air entering through the windows.

I understand that a recent order from the office of the Supervisor of Janitors of the Public Schools of the City of New York prohibits the opening of windows in classrooms except for the fifteen-minute period of exercises when the blowers are not in use. It is claimed that the opening of one classroom window destroys the effectiveness of the ventilating plant and interferes with the proper circulation of air in all parts of the building. If this should really be so then I would appeal to the Chairman of the Committee on Buildings to insist that the ventilating system be shut off at least once every hour for ten to fifteen minutes, so that the windows can be opened. In view of the great amount of dust which is brought into the classroom on the shoes of hundreds of children, I have serious doubts whether the most perfect ventilating system, without the frequent opening of windows, would be free from danger. I am convinced that your board is most anxious to do the best it can for your and your pupils' welfare, and that this order will soon be modified. With you personally I wish to plead not to be afraid of draughts. The air coming in with draughts is pure and has never injured or killed anybody. With the exception of exposure when greatly overheated to very cold currents of air, nothing is to be feared from the pure air carried in by draughts. Neither you nor the children are likely to be overheated by sitting still in the classroom. Nowadays we do not only expose our tuberculous patients constantly to cold air, or even to the wind, but include pneumonia patients in our cold open air treatment, and even the smallest children suffering with pneumonia are benefited thereby. Professor Wm. P. Northrup of Bellevue Hospital Medical College recently reported to the County Medical Society some of the most gratifying results obtained from cold air in the treatment of children suffering from pneumonia.* If it does not hurt but benefit the pneumonic child to breathe direct fresh air, it surely must be beneficial to the healthy pupil attending the public school and to the teacher as well.

Some of you, nay, let me hope, all of you, except those who give up their career for vital reasons, will be superintendents of schools, or become so influential that the selection of sites for school houses and the construction and equipment of the same will be one of your tasks and privileges. The essentials of constructing a modern school are well known to all sanitarians and up-to-date architects.

In relation to the prevention of tuberculosis, I would suggest only a few points. Where the site or locality does not permit of having a large playground a roof garden which can be covered in winter is absolutely necessary. Instead of our American windows, which can only be opened to one-half of their extent, I would wish to see French windows in every schoolhouse, or windows that slide into the wall, or those that turn on a pivot, all of which permit twice the amount of foul air to go out and of good air to come in that our ordinary windows do. Heating and general ventilation of schoolrooms

* Northrup, Wm. P.: "The Cold Fresh Air Treatment of Pneumonia." Paper read before the County Medical Society of New York, January 22, 1906.

should, of course, be of the most improved kind. The walls and woodwork of schoolrooms should be plain, to make the accumulation of dust virtually impossible and the cleaning easy. All corners should be rounded off, and the walls painted. The interior equipment, that is to say, the school furniture, benches, and desks, should be so arranged that they can be easily moved or folded together, so that a thorough cleaning of the floors is made possible after each daily session. It goes without saying that the drinking-cup should be replaced by the hygienic drinking fountain, which makes the use of a cup unnecessary, and thus eliminates one method of transmission of microbic disease.

Every public school should have a well-equipped gymnasium and a swimming tank with constantly running fresh or salt water, warmed to a suitable temperature in winter. Each pupil should be given the opportunity to bathe several times during the week. To learn to swim should be made obligatory and every class should be supervised by a competent swimming master. Leaving aside the great hygienic gain to be derived from such an installation, especially when the pupils are recruited from homes where bathrooms are rare and where regular bathing is considered superfluous, the swimming lessons will be of value to every boy and girl, and in case of such disasters as the recent *Slocum* tragedy, there will be a much smaller loss of life. There is hardly a college in existence in America where the gymnasium and the swimming tank do not form an important part of the equipments, and a college without them would surely suffer in prestige. The public school where the children of the masses receive their education should not be behind the private college in its equipments.

I am convinced not only that the public school which has a well-equipped swimming establishment and which makes regular bathing and instruction in swimming obligatory for every pupil will have fewer cases of infectious and contagious diseases, particularly scrofula and tuberculosis, but that the intellectual and moral status of its pupils will also be higher.

I beg you, when once in command, not to forget that physical exercise, outdoor life, and when indoors, as much fresh air as possible, are most essential to the normal development of the child. There is too great a tendency in the present age to develop the intellect of our children to the detriment of their physical welfare. They work too much, they do not play enough, and they sleep too little. This overwork, because of too many school hours and too many lessons at home and loss of sleep, are responsible for our national disease, neurasthenia, particularly perceptible in the young. I was deeply impressed when reading the recommendations formulated by the committee appointed by the French government and the city of Paris* with a view to diminishing tuberculosis among its school children, by the fact that they insisted upon a minimum of nine to ten hours sleep, according to the age of the child.

While all the organs of the child should be given opportunity for full development, the respiratory system should receive particular care and attention. I would suggest that breathing exercises should not only be taken now and then, but that they should form an important item in the curriculum of all the schools. I do not believe that there is any better, greater and more efficacious barrier to becoming consumptive than a good pair of lungs, and it would seem to me that it should not only be a great duty, but also a great privilege and pleasure, to make a strong and vigorous man or woman out of a weak-lunged child, who may be predisposed to tuberculosis.

I do not know what system of breathing exercises you have been taught, but, if you will permit me, I will demonstrate to you those which I have found to be most valuable in my work among families where I had some apprehension as to the children becoming consumptive. In fact, I teach these exercises wherever and whenever I can, for I think they do good even to a well person, and, with some modification, I teach them also to my consumptive patients.

In front of the open window, or out of doors, assume the position of the military "attention," heels together, body erect, and hands on the sides. With the mouth closed, take a deep inspiration (that is, breathe in all the air possible), and while doing so raise the arms to a horizontal position; remain thus, holding the air inhaled for about three to five seconds, and while exhaling bring the arms down to the original position. This act of exhalation, or expiration, should be a little more rapid than the act of inspiration. When this first exercise is thoroughly mastered and has been practised for several days, one may begin with the second exercise, which is like the first, except that the upward movement of the arms is continued until the hands meet over the head.

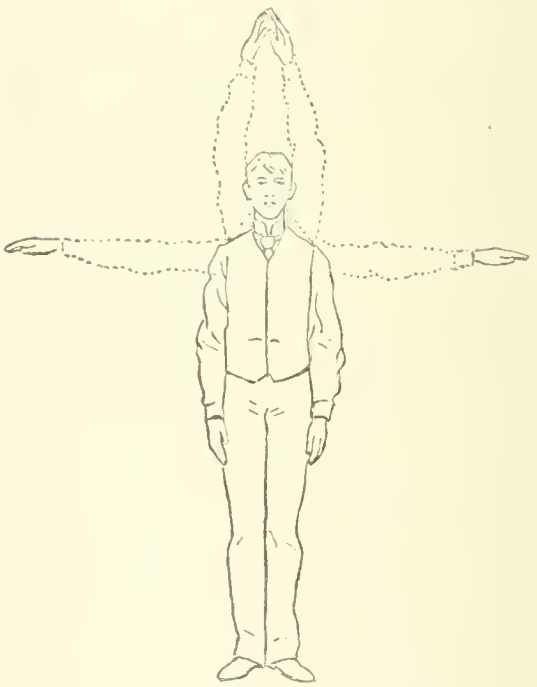

Fig. 1.—First and second respiratory exercise.

The accompanying illustration (Fig. 1) shows the positions which are to be taken during those two exercises. The third breathing or respiratory exercise, which requires more strength and endurance, should not be undertaken until the first two have been practised regularly several times a day for a few weeks, and until an evident improvement in breathing and general well-being has been observed. We will endeavor to make this third exercise, which might be called a dry swim, more comprehensible by the illustration (Fig. 2). Take the same military position of "attention," and then stretch the arms out as in the act of swimming, the backs of the hands touching each other. During the inspiration move the arms outward until they finally meet behind the back. Remain in this position a few seconds, retain the air, and during exhalation bring the arms for-

Zeitschr. f. Tub. u. Heilstattenwesen, Vol. VII, Bd. 2, p. 197.

ward again. This somewhat difficult exercise can be facilitated and be made more effective by rising on the toes during the act of inhalation, and descending during the act of exhalation.

Of course, when out of doors one cannot always take these exercises with the movement of the arms without attracting attention; under such conditions

Fig. 2.—Third respiratory exercise.

raise the shoulders, making a rotary backward movement during the act of inhaling; remain in this position, holding the breath for a few seconds, and then exhale while moving the shoulders forward and

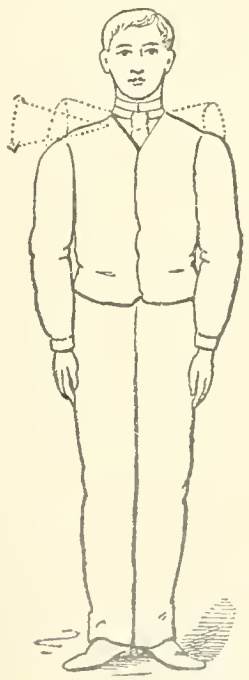

Fig. 3.—Respiratory exercise with rolling of shoulders.

downward, assuming again the normal position (Fig. 3). This exercise can easily be taken while walking, sitting, or riding in the open air.

Young girls and boys, and especially those who are predisposed to consumption, often acquire a habit of stooping. To overcome this, the following exercise can be recommended: The child makes his best effort to stand straight, places his hands on his hips with the thumbs in front, and then bends slowly backward as far as he can during the act of inhaling. He remains in this position for a few seconds, while holding the breath, and then rises again somewhat more rapidly, during the act of exhalation (Fig. 4).

Few people have a just estimation of the value of these exercises. From your studies in physiology you will remember that the amount of tidal air—that is to say, the volume which is inspired and expired in quiet respiration—is only 500 c.c., the complemental air—the volume which can be inspired after an ordinary respiration—1,500 c.c., and the supplemental air, or reserve air—the amount which can be forcibly expelled after an ordinary respiration—amounts to 1,240 to 1,800 c.c. Thus one can readily appreciate the effect of these exercises on the physiological action of the lungs by increasing the supply of oxygen (O), and more effectually removing the carbonic acid (CO_2). You will remember that these interchanges of gases in the lungs result in the conversion of venous into arterial blood. The scientific name for this process is hematosis.

Fig. 4.—Exercise for people in the habit of stooping.

The following general rule concerning breathing exercises should always be remembered: Commence with the easier exercises and do not go on with the more difficult ones until the former are completely mastered. For healthy school children I would suggest to take from six to nine deep respiratory exercises, either of one kind or the other, every hour.

A second general rule is never to take these exercises when tired, and never to continue them so long as to become tired. It is, of course, self-understood that these exercises should always be taken in an atmosphere as pure, fresh, and free from dust as possible, and that no restricting garments around the waist or neck should be worn. You as teachers should know that constricting the chest or abdomen will often leave lasting injuries to the vital organs incased in the thoracic and abdominal cavities.

Mouthbreathing in children, and sometimes in adults, is often caused by certain growths in the throat (adenoid vegetation), by enlarged tonsils, or by growths in the nose (polypi, etc.). The removal of these obstructions by surgical aid is perhaps the

only rational method to assure natural breathing. Incidentally, we may be permitted to say that these operations are not at all dangerous; but by the presence of vegetations in the throat (retropharynx) the hearing and the intellectual and bodily development of the child may become seriously impaired. The early removal of such growths should be earnestly recommended. If you observe among your pupils a chronic mouth breather, call the attention of the school physician or the parents to the child and explain to the parents the danger of a neglect in this matter. The respiratory exercises just described are particularly useful for such children after operation, otherwise they often retain the habit of imperfect breathing which they had acquired.

In teaching the children under your charge how to breathe, sit, stand, and walk properly, you teachers do perhaps more toward the prevention of tuberculosis than all we physicians together. I would love to see singing and outdoor recitation at proper seasons incorporated in the curriculum of every school in city and country, and city schools should have commodious roof gardens for that purpose. Wherever there is a playground it should be kept clean, as free from dust as possible, and be daily strewn with clean sand or gravel. Children should be warned not to expectorate on the playground, and adults should be severely punished by law for so doing.

The breathing exercises at school should, of course, be supervised by teachers. Modern school hygiene, particularly in the United States, is far superior to what it has been in the past, yet there is still room for improvement. As far as the prevention of tuberculosis is concerned, permit me to suggest to you the advisability of giving the children leaflets of instruction. I know this practice to be in vogue in some schools in this and other States, but the leaflets I have seen seemed rather incomplete. Let me give you here a tentative leaflet which I have written with the particular view of preventing consumption.

Every child and adult can help to fight consumption. School children can be helpful by complying with the following rules:

Do not spit, except in a spittoon or a piece of cloth or a handkerchief used for that purpose alone. On your return home have the cloth burned by your mother, or the handkerchief put in water until ready for the wash.

Never spit on a slate, floor, sidewalk, or playground.

Do not put your fingers into your mouth.

Do not pick your nose or wipe it on your hand or sleeve.

Do not wet your finger in your mouth when turning the leaves of books.

Do not put pencils into your mouth or wet them with your lips.

Do not hold money in your mouth.

Do not put pins in your mouth.

Do not put anything into your mouth except food and drink.

Do not swap apple cores, candy, chewing gum, half-eaten food, whistles, bean blowers, or anything that is put in the mouth.

Peel or wash your fruit before eating it.

Never cough or sneeze in a person's face. Turn your face to one side and hold a handkerchief before your mouth.

Keep your face and hands and finger-nails clean; wash your hands with soap and water before each meal.

When you don't feel well, have cut yourself, or have been hurt by others, do not be afraid to report to the teacher.

These leaflets should be read and re-read by the pupils and explained and commented upon by the teacher. Children should be not only allowed, but rather urged, to take these leaflets home and show them to their parents. Thus, these little ones may become missionaries in homes where cleanly habits and domestic hygiene have been heretofore unknown.

In schools where slate- and lead-pencils are given to the children and collected after school hours, these articles should be disinfected before they are again distributed to the pupils. Not only the spread of tuberculosis, but far more contagious diseases, such as measles, diphtheria, and scarlet fever, may be prevented among school children by this simple precaution. The custom in vogue in some schools of having every child use a suitable envelope, so as always to have the same pencil, while preferable to no precaution at all, is, in my opinion, not nearly so safe as a thorough disinfection.

Another method of teaching school children the prevention of tuberculosis has been inaugurated in France in a most ingenious way. My distinguished teacher, Professor Letulle, suggested to the Minister of Education of France that the covering of the books used by school children should serve as a means of instructing the pupils concerning the prevention of tuberculosis. He himself wrote the two pages of instruction for that purpose. The outside cover represents the exterior of a sanatorium, and the text is illustrated by a number of pictures. Permit me to give you here the translation of the subjects which are treated in a most concise and comprehensible way on these two pages: "The air we breathe and the respiratory organs"; "Tuberculosis decimates humanity"; "Tuberculosis is contagious"; "Tuberculosis and its microbe"; "Robert Koch, the discoverer of the microbe of tuberculosis (consumption)"; "Tuberculous infection from man to animal and from animal to man"; "Tuberculosis can be prevented"; "Sure way to prevent consumption"; "Never use strong drinks"; "Tuberculosis can be cured"; "Tuberculosis is a social disease."

An important point in the prevention of the disease under consideration among school children is, to my mind, that the school teacher should be familiar with the objective signs and symptoms of tuberculosis and the characteristics of a person disposed to consumption. These signs are a persistent cough, feverish face, becoming easily tired, or at times an increased excitability, and on the discovery of these symptoms take such steps as are indicated. As is well known, tuberculosis of the bones and joints is relatively and absolutely more frequent in children than pulmonary complications. Lameness or easy tiring of arms or legs is often the beginning symptom of bone tuberculosis. A slight pressure in the region of the joints causes a sudden severe pain. If the spinal column is affected, the symptoms will depend upon the location of the vertebra which is attacked by the disease. For example, if this should be in the region of the neck, there will be difficulty in swallowing, in breathing, or a frequent dry cough. If any of the vertebræ in the region of the chest is affected, a feeling of constriction like a tight band around the chest will be observed, accompanied often by digestive troubles. If the seat of the disease is in the lower portion of the spinal column, there will be irritation of the bladder and lower bowels, an inclination to much urinating, and radiating pains toward the hips. If any such symptoms are discovered by the school teacher, the school physician and the parents should be notified.

Scrofulous children are found particularly frequently in the districts of the poor, and the teacher should know that scrofulosis is only a lighter type of tuberculosis, but it is tuberculosis, and that it can be successfully treated and cured by fresh air, sunshine, good food, and improving the general hygienic environments. The scrofulous child is usually pale, with flabby skin and muscles. The glands around the neck are swollen, and skin disease, sore eyes, and running ears are frequent symptoms. The little patient usually manifests a phlegmatic condition, but we might also find some that are nervous and irritable. The latter often have a particularly white, delicate skin, which makes the veins visible. Fever may be observed in some scrofulous children. In view of the happily very curable nature of scrofulous affections, the importance of the early recognition and of the timely and judicious treatment is, of course, self-evident.

In speaking of scrofulous and tuberculous children of the poor, I must revert once more to the duties of the school board; for what can the teacher or the superintendent do with the underfed children of the poor attending our public schools? Breathing exercises will not supplement their lack of food, but, if anything, they will increase the appetite of the pupil, and a cracker and an apple are not enough for a growing boy or girl, and altogether too little to make their cheeks red.

In an address which I had the honor to deliver some years ago before the Teachers' College of the Columbia University, and in another address before the American Academy of Medicine, a year later, on the subject, "How May the Public School be Helpful in the Prevention of Tuberculosis?" I suggested to the board of education a philanthropic enterprise in which the generous and good-hearted people of every city would most gladly join. This was to provide the half-starved little ones with a luncheon of a few good meat sandwiches and a glass of milk, and I stated that this practice, which had been inaugurated in Berlin a year before, had resulted in a marked improvement in the physical, intellectual, and moral condition of the children. They did better work at home and at school. To avoid a pauperizing tendency, a few pennies should be charged for this luncheon. This practice is in vogue in the city of Boston and works most satisfactorily.

How delighted was I when I read in our daily papers a few weeks ago that your indefatigable superintendent, Dr. Wm. H. Maxwell, had taken up this matter, and that ere long our beloved city will be ahead in such a truly philanthropic enterprise as it is ahead in so many other humanitarian institutions. Permit me here to quote from the *Globe* of November 16, from an article on this subject. With characteristic New York newspaper directness, its headlines read:

"WANTS PUPILS FED.

"They Can't Study on Pickles and Candy, Says Dr. Maxwell, So Board Should Feed Them.

"Must Pay for What They Eat.

"Prices Will Be Low, So That Children in Poorer Districts Can Get Wholesome Midday Meal.

"PUPILS' LUNCHEONS AT SCHOOL PRICES.

Coffee, a cup	2 cents.
Roll	1 cent.
Soup and roll	3 cents.
Milk, a glass	2 cents.
Cake	1 cent.
Pie, per cut	2 cents.

"Coffee at 2 cents a cup, milk at 2 cents a glass, bread and soup at 3 cents a plate may be a part of the bill of fare to be offered in lunch rooms in the public schools, if the Board of Education adopts the suggestion made by City Superintendent William H. Maxwell. Wholesome food at minimum cost should, he believes, be furnished to the pupils in the public schools.

"Thousands of children are not properly fed, and their school work suffers in consequence. Poverty is not the sole cause for such a condition. Ignorance of parents as to proper preparation of food is largely responsible for it. Another contributory cause is that mothers, forced to leave their homes early in the morning for work, prepare breakfasts for their children, but the children, left to themselves, sleep too late, and have to hurriedly eat their breakfast or leave without it. Then, too, it has been found that pupils whose parents have given them a few cents to purchase their luncheons spend it for candy or big pickles.

"These and other children should be given an opportunity to purchase good food, and to that end the Board of Education, according to Dr. Maxwell, should provide lunch rooms in every public school, particularly in the poorer sections of the city. There the pupils should be able to get a good, wholesome midday meal at cost, or at as low a cost as possible.

"The Board of Education now makes provision for lunch rooms in the high schools, where caterers, under the supervision of the principals, sell hot dishes and other food to the pupils, many of whom bring the greater part of their luncheon from home. Chairman Samuel B. Donnelly, of the committee on care of buildings, states that the plan suggested by Dr. Maxwell, as an extension of that now in operation with high schools is feasible.

"Dr. Maxwell made the suggestion that school lunch rooms be provided, at Cooper Union last night, in the course of the discussion which followed his address on "The Teacher's Opportunity," given under the auspices of the lecture bureau of the Board of Education. It was suggested by a man in the audience that Dr. Maxwell appeal to the rich to provide funds for the proper feeding and clothing of the thousands of children now underfed and underclothed.

" 'While I believe,' replied Dr. Maxwell, 'that some provision should be made to feed the children, I also believe that under no condition should an appeal be made to the charity of the rich.' He called attention to his suggestion made at St. Louis last year, that the Board of Education should feed the pupils, 'but,' he added, 'I do not seem to have convinced many members of the Board of Education.' He thereupon suggested that the Board of Education would do a good service to the cause of education were it to make it possible for school children to purchase a wholesome midday meal."

You see, I do not stand alone with my views on a good luncheon for the school children, but Mr. Maxwell, and also Mr. Donnelly, of the committee on the care of buildings, are strongly in favor of this philanthropic scheme.

While I know I am addressing teachers, I know that I am also addressing the citizens of a great community and of the greatest republic, and as such I appeal to you to make your influence felt wherever you can to combat that great predisposing factor to tuberculosis in childhood—child labor, which, we must confess to our shame, is still permitted in many of our States. Proclaim everywhere, whenever you can, that nothing predisposes a child's delicate and growing organism to tuberculosis more than the

great physical strain produced by hours, and often long hours, of indoor labor, which time the child should spend in play outdoors. Child labor makes physical and nervous wrecks of normal children, and because of its influence on the nervous system of the growing boy and girl, I hold it responsible for a good deal of alcoholism among our young people.

President Roosevelt, in his recent message at the opening of the last session of Congress, recommended in strong terms a model child labor law, in order that Congress might set a worthy example to the States in which it has no power to legislate on this subject, by wise and discriminating legislation for the District of Columbia, over which it has the necessary power. Permit me to read to you a few suggestions from an appeal issued recently by the National Child Labor Committee,* which, I think, speak for themselves:

"We request the friends of the twenty-nine million children under 16 years of age in the United States, for whose industrial guardianship and for the protection of whose rights to healthy physical development, education, and leisure the National Committee is organized, to cooperate in recommending this bill to the favorable attention of their members in Congress. It will mean much for our cause in every State to have at the National Capital a reasonably strong and fair law on the subject of child labor. Members and friends of local child labor committees, of educational, charitable, and philanthropic societies, of women's clubs, and all other organizations interested in this movement, are earnestly requested to write at once to their respective senators and members of Congress, sending them, if possible, the enclosed copy of the bill to be presented, and urging the passage of this bill."

I have thus far spoken to you only of the prevention of the disease, but you will recall that at the beginning of my discourse I emphasized the fact that the disease was a curable one. I have not yet told you how consumption is cured at the present time. Consumption is not, nor never has been, cured by patent medicines, nostrums of any kind, or faith cure. Not even individuals who practise under the portentous name of Christian Science, and who, if they do not lack in Christian virtue, I am certain lack in science, are capable of curing tuberculosis. I know that the Christian Science healers, in their dealings with consumptives disregard all hygienic precautions against the spread of the disease: they regard all symptoms as non-existent, and they even try to make the patient believe that when he has a hemorrhage, when he sees his life blood flowing away, that it is only so in his imagination and that in reality such a thing as a hemorrhage does not exist at all. To my mind, the person who, without any medical or hygienic education, dares to attempt to treat so serious a disease as tuberculosis and intentionally even disregards the fundamental principles of preventing this or other communicable diseases, is a criminal and an enemy to his fellowmen.

The conscientious physician of to-day treats pulmonary consumption by the scientific and judicious use of God's fresh air, day and night, of sunshine, pure water, inside and outside, abundant and good food (milk, eggs, meat, vegetables, fruit), and the help of certain medicinal substances when the just-mentioned hygienic and dietetic means do not suffice in themselves to combat the disease—and all this under constant medical supervision, either at home or in a sanatorium.†

The sanatorium is an institution specially built and equipped for the exclusive treatment of tuberculous patients. What is most interesting to know is that this cure can be accomplished not only in California or Colorado, but also in our own home climate. While I am far from depreciating the value of high altitudes, much sunshine and a clear atmosphere as adjuvants, I must confess that in my experience the cures obtained in our so-called ordinary home climates, while often requiring a little longer time, seem to be more lasting than those obtained in more congenial climes. When we consider that the majority of consumptives come from the laboring classes, and that for obvious reasons they must be treated and cured in a climate where they will have to live and labor after their restoration to health, we will see that the multiple establishment of sanatoria near large centers of population, independent of special climatic advantages, will help most materially toward the solution of the tuberculosis problem. In this conviction I do not stand alone. Such men as Letulle of France, Dettweiler and von Leyden of Germany, Biggs, Otis, Flick, Richer, and others of our own country, have expressed themselves as being of the same opinion.

Again, I am convinced that by placing the people's sanatorium near large centers of population, the depressing factor produced by an often severe form of nostalgia is done away with. The thought that he is near his family and friends always has a beneficial influence on the patient.

In connection with the cure of tuberculosis I have already warned you against the remedies containing alcohol which are advertised as sure cures for consumption. Unfortunately, the sure consumption cures are not limited to the people who only use alcohol as the main constituent of this treatment. Had I the time, I could tell you of some of the dangerous constituents on the one hand, and the utterly useless substances on the other, which are put into remedies widely advertised as cures for consumption.

Unfortunately, the public press serves for the advertising of many "absolutely sure consumptive cures," which are from time to time put on the market by unscrupulous quacks. I am nevertheless sanguine enough to hope that in time the better class of newspapers will, in the interest of the community at large, no longer extend the hospitality of their columns to such dangerous advertising matter, especially when it is protested against by the intelligent reader. How many poor consumptives have lost their last little reserve fund by giving everything they had for a dozen bottles of the "sure and quick cure," only those who come much in contact with them know. How unscrupulous some of these charlatans are in their method of procuring certificates of cure, which they then publish as bait to the unfortunate, help-seeking sufferer, is something which can hardly be believed. Let me tell you of one instance: A poor woman in the last stages of consumption came to me seeking advice. When asked for the name of her former medical attendant, she confessed that she had been treated for a number of weeks by a quack concern, and now, her means being exhausted, she was made to understand that they would not continue to treat her unless she would give them a

* This appeal was accompanied by a copy of a most excellent bill proposed to regulate the employment of child labor in the District of Columbia.

† I use the word sanatorium in preference to the word "sanitarium" for the following reasons: Brehmer, the founder of the first institution of that kind, called it "Heilanstalt," which means a healing institution; and the word "sanatorium," from the Latin *sanare*, to heal, gives certainly a better equivalent to the German word than the word "sanitarium." This latter word is derived from the Latin *sanitas*, health, and is usually employed in this country to designate a place considered as especially healthy, a favorite resort for convalescent patients, or an institution for the treatment of mental or nervous diseases.

certified testimonial that she had been thoroughly cured of her disease, which had been pronounced an advanced case of consumption by prominent physicians. This poor sufferer had not derived any benefit whatsoever from the treatment, and as a result her conscience would not permit her to become a partner to such a fraudulent procedure.

And now a last but very earnest word on what to do with the tuberculous school child and the tuberculous teacher. A number of States have taken very radical measures in this respect. My interest in the subject was first aroused by a letter received last February from my friend, Dr. Herbert Maxon King, the physician-in-chief of the Loomis Sanatorium at Liberty. He sent me a clipping announcing the decision of the Board of Education of Jersey City, that no teacher having consumption would hereafter be allowed to teach in a public school. In commenting on this decision, Dr. King said: "It occurs to me that if such action shall be taken on the part of the various boards of education throughout the country, much injustice is going to be done." Since then, according to the MEDICAL RECORD of November 25, 1905, the State of Iowa, and, according to the *Medical News* of December 30, the State of Illinois, have joined the list of those that exclude tuberculosis from the public schools, and these boards have issued an order notifying the superintendents of schools throughout the State to exclude all teachers, pupils, and employees suffering from the malady. They exclude the teacher and they exclude the child, and I approve of this decision, but I must ask: Have those States which exclude the tuberculous teacher, who nine times out of ten has contracted this disease in the performance of his or her duty, provided a pension for her, so that she can devote a year, or perhaps more, to doing nothing but getting well? Or has she been able to accumulate enough means to live the rest of her life without care in case she will not be cured entirely and not readmitted in the school? I doubt if this will be the case in many instances. The French commission above referred to was requested to look into this matter and recommended that the tuberculous school teachers should receive, for at least three years, a sum sufficiently large to provide for proper sanatorium treatment, or judicious treatment at home, and this without losing the right to be pensioned later on. And what is done in our American schools for the children who are tuberculous? How many seaside or inland sanatoria for tuberculous children have we where the child can become cured of its infirmity and concomitant with its physical improvement receive its intellectual education? We in this great city of New York have just one seaside sanatorium for tuberculous children which fulfills this mission, but its capacity is limited to 54 beds, and we have in New York about six thousand tuberculous children needing sanatorium treatment.

I have said before that I approve of weeding out the tuberculous child and the tuberculous teacher from our public schools, and I go even further and recommend an examination for tuberculosis of every child and teacher entering the public school and a periodical examination of both, but I also believe that it is our most sacred duty to provide for these tuberculous teachers and tuberculous children. Let us multiply our sanatoria for children and employ in them as many teachers as we can from the unfortunate ones who have contracted tuberculosis.

Now, what are we to do with the rest, who cannot find employment in these institutions? One of our most beloved, large-hearted and generous philanthropists and distinguished fellow townsman, Mr. Andrew Carnegie, recently created a fund to pension teachers in academic schools who are beyond a certain age and no longer able to earn their livelihood. Mr. Carnegie very justly surmised that our college professors are, as a rule, too poorly paid to accumulate a sufficient fortune to live in comfort during their reclining years. This is a grand and beautiful philanthropy, and I sincerely hope that the example of Mr. Carnegie may be emulated by other philanthropists; but I hope and pray that in future gifts for pensioning educators our ordinary school teachers will not be forgotten. They must have served at least twenty years before they are entitled to any pension, and then it is but small. Then they, too, have often very little chance to accumulate enough to enable them to live in comfort during old age; and I am certain that when misfortune strikes one in the prime of life, when the school teacher contracts tuberculosis and must leave the school, nine times out of ten she will have very little or no money saved. Yet it costs money to provide for at least a year in which to cure a tuberculous patient, and it requires even more to make him comfortable when he is not curable but is forced to live in idleness for two years or more. Let the municipality which excludes the tuberculous teacher and the tuberculous child provide school sanatoria for the children, and, whenever possible, employ therein the tuberculous teachers in the earlier stages of the disease. Let our good and generous fellow citizens who love to devote part of their wealth to the relief of the suffering and misery of their fellowmen, remember in their benefaction the school teacher who has had the misfortune to contract consumption. Whether such a benefaction be in the shape of a special sanatorium for tuberculous school teachers or a special fund whereby these school teachers can be sent to existing sanatoria, or be treated at home, is immaterial. The men and women who will direct their philanthropic efforts toward such a noble purpose will surely serve their fellowmen in the highest degree possible, for next to his Creator and his parents, to whom is man more indebted for what he is and what he knows than to you, his teachers?

16 WEST NINETY-FIFTH STREET.

SOME NECESSARY PRINCIPLES IN THE DIAGNOSIS OF SURGICAL CONDITIONS OF THE UPPER URINARY TRACT.*

BY J. BAYARD CLARK, M.D.,

NEW YORK.

GENITOURINARY SURGEON TO BELLEVUE HOSPITAL OUT-PATIENTS, ASSISTANT SURGEON TO TRINITY HOSPITAL.

IT seems appropriate just now to group in a useful sequence such methods, both old and new, as have proved themselves valuable in making diagnoses in affections of the upper urinary tract. For with the advent of newer appliances, such as the ureter catheterizing cystoscope, the various appliances for intravesical separation of the urine, and the improved *x*-ray apparatus, there is a tendency to accept too confidently the evidence that any one of these instruments alone may give, without giving due weight to those preliminary steps in the process of diagnosis which lead up to the point where these later date instruments are of real value.

Unfortunately the idea is becoming prevalent that urinary diagnosis has become by the aid of mechanical appliances a matter both simple of execution and rapid of completion. It is true

*Read before the Newark, N. J., Medical and Surgical Society, November 16, 1905.

that, by the added usefulness of the improved appliances which we now have, diagnoses are made possible which before were impossible; but it is out of the question to hope to arrive at satisfactory conclusions in difficult cases without expense of time and study, both clinically and in the laboratory. Therefore those who would look for good results in their endeavors to define the site and determine the character of pathological conditions of the urinary system should be prepared to spend both time and thought in the elucidation of those problems.

Before detailing an order of procedure in diagnosis, it would be in place to speak of the use of the cystoscope, or rather what has been a misuse of that instrument. Knowing a number of instances where the ureter catheterizing cystoscope of different makes and varieties was used as a universal instrument for the exploration of the bladder as well as an aid to diagnosis in ureter and kidney affections, I was led to further inquiry, and experienced the greatest surprise when I learned from the instrument makers how many more ureter catheterizing cystoscopes were sold here in America than those of the simple examining type.

A well-known firm in Berlin, who manufacture the Nitze instrument only, have sold in the United States 800 ureter catheterizing cystoscopes and 350 simple examining cystoscopes. A large importing and manufacturing concern of this city give as their comparative sales: "Three catheterizing cystoscopes to one of the plain examining." A New York house has, for some six or seven years, been manufacturing the Tilden Brown composite cystoscope, which consists of a common sheath with telescopic tubes for direct view catheterizing, and a prismatic telescope for observation. This cystoscope has not the unpleasant feature which the prismatic catheterizing instruments have of a shoulder directly behind the beak on the shaft. It is only within the past year that this company has perfected the Otis cystoscope, which is a simple examining instrument of the prismatic type.

This is certainly very suggestive evidence that a good many physicians are buying and using the more complicated instrument who have never learned to handle the simple one. The reason for this is perhaps not difficult to explain. The recommendation and description by the instrument dealers of how the ureter catheterizing cystoscope can serve the double purpose of exploring and catheterizing have led many whose knowledge of cystoscopy is mainly theoretical to buy a cystoscope of the catheterizing variety without giving the matter much serious thought.

The following reasons will make evident, I think, why the use of the ureter catheterizing instrument is never justified until indication for its employment has been elicited by the simple prismatic cystoscope.

First. From the standpoint of the patient's comfort, a very important consideration, I believe, there is no catheterizing instrument made that can be introduced with as little discomfort as any one of several simple examining cystoscopes of prismatic type, averaging 21 by the French scale, and with an even, rounded shaft, and a gently angulated beak. All the useful catheterizing cystoscopes are considerably larger of caliber, and in some varieties the shoulder near the beak for the egress of the catheter or catheters is an added source of discomfort.

Second, from the operator's standpoint. The simple cystoscope is more readily sterilized. It is more easily handled and introduced. In strictured or naturally small urethræ it is often the only cystoscope that can be introduced. In diseased urethræ, or where there is prostatic enlargement, the minimum of traumatism is important. The simple cystoscope gives a *clearer* and a *larger* field of vision. It is therefore possible to arrive at a much more accurate interpretation of the condition of the bladder, the state of the ureteral orifices, and the character of the fluid emitted.

The knowledge gained by the simple instrument may be sufficient for the diagnosis, and catheterism of the ureters or the use of the catheter cystoscope would then be distinctly contraindicated. It is only in those cases where a ureteral catheter *has* to be employed that we are justified in the use of the instrument for that purpose. Dr. Max Nitze, of Berlin, makes it an unfailing rule (where the cystoscope is to be used) first to explore the bladder with the simple prismatic instrument. In the writings of Mr. Hurry Fenwick, of London, the simple prismatic cystoscope stands out with such importance in the diagnosis of kidney as well as bladder affections, that one cannot fail to appreciate the great value in his hands of this instrument as a diagnostic means, even to the practical exclusion of the ureter catheterizing cystoscope. If one intends to do cystoscopy and hopes for good results in this line of work, he will first possess himself of, and learn to use, the simple prismatic cystoscope.

A word concerning the use of intravesical urine segregators. There are undoubtedly cases where these instruments can be employed to advantage, but never with that accuracy which comes when the urine is collected directly from each ureter with a catheter. When these instruments are used, it is essential to precede their employment by cystoscopy in order to determine whether their use is worth while, as intravesical enlargement of the prostate and abnormally placed ureters render the instruments useless.

Concerning the detection of calculi in the ureter or kidney, the *x*-rays are probably our most reliable guide, but we must be guarded in our decisions about shadows lying in the path of the ureter. Such shadows have quite frequently of late been seen, and an operation been performed, no stone being found in the ureter. These shadows may be phleboliths, artifacts, or sesamoid bones. By introducing a styletted catheter into the ureter and then taking a radiograph, we can better determine the situation of shadows that are apparently those of stones in the ureter.

In setting down the following course of procedures necessary to a diagnosis, the description of instruments and laboratory appliances and of the technique used in their employment is purposely omitted, in order that this paper may not be too long.

Although it is unnecessary to enumerate here all the surgical diseases to which the kidney and ureter are liable, it is well to mention the affections which should always be kept clearly in mind. Renal tuberculosis, primary and unilateral, perhaps heads the list of those conditions which seem to evade a timely diagnosis. The lack of patient and repeated search for the tubercle bacilli and the lack of proper diagnostic measures must be held responsible for failures in diagnosis in the majority of cases. Pyelitis and pyelonephritis, the variety of which complicates and so often succeeds the infected bladder, the infection of which is due to urinary obstruction by

prostatic enlargement or strictured urethra, must be looked upon as not uncommon. Pyonephrosis is but the terminal stage of the preceding conditions, plus a certain number of cases of hydronephrosis in which infection follows. Other forms of pyelitis and pyelonephritis are those by infection upwards, not consequent upon an obstructed urinary flow, and those in which infection occurs by means of the lymph or blood current. The pyelitis of pregnancy should also be remembered.

The *Bacillus coli communis* is perhaps the commonest bacterial agent. Pyelitis due to the gonococcus may be looked upon as rare. It should be remembered that the renal pelves are made more liable to infection by the presence of calculi.

The diagnosis of kidney stone is perhaps less difficult than that of many of the other affections of these organs, but nevertheless many mistakes are made in a too hurried verdict on the supposed condition. Stones in the ureter are looked upon as much more common than they formerly were, and their diagnosis is certainly under better control. The foregoing may represent the conditions usually to be thought of first. Less common surgical diseases of the kidneys are new growths, cysts, actinomycosis, and injuries due to external violence.

Of the ureters, strictures, kinks, and closure of the lumen by the presence of tumors are conditions met with from time to time.

When a patient comes to us with one or more of the following complaints or signs, we naturally turn our attention to the urinary system: Pain along the course of the urinary tract; disturbances of the act of micturition; pathological conditions of the urine evinced by the presence of blood, pus, albumin, bacteria, etc.

The first step should be an explanation to the patient of the fact that in troubles of this nature an accurate knowledge of the condition is essential. In many instances it requires patience and time in order to collect the evidence necessary for a diagnosis. Preparing the patient's mind in this way at the outset is much better than promising an early diagnosis and losing the patient's confidence by a failure.

It is folly to give an opinion without having had sufficient opportunity for observation. For example, there are cases where the finding of the tubercle bacilli must determine the lesion, cases in which we must repeat our instrumental examination, cases where fever or pain masks the evidence we seek, and cases where the secretion of the kidneys change from day to day.

The history, both general and urinary, cannot be too carefully taken and written down. The physical examination should be a general one, not focusing our attention too keenly upon the urinary tract until we have satisfied ourselves as to the patient's condition as a whole. Proceeding then to the genitourinary organs, if the patient is a male, the external urinary meatus is inspected, so that a smear or culture can be taken if it is deemed necessary. He is then requested to pass his urine into two or three glasses. Immediately after this, if the history is suggestive of the presence of residual urine, he is catheterized to determine its amount.

This time for getting the specimens of urine is carefully chosen before we proceed to palpation of the kidneys, ureters, bladder, seminal vesicles, and prostate, otherwise the evidence we seek from the urine, as it is usually passed, might be very considerably changed by elements artificially expressed during the palpation of these organs.

Having obtained these preliminary specimens of urine we continue the examination by inspection and palpation. We start with the kidneys, ureters, and bladder. Then the external genitalia are examined, and finally the rectal and bimanual examination of the prostate, seminal vesicles, and bladder is performed. If the patient is a female, the preliminary specimens of urine can be collected by the catheter, after which we can make the physical examination of the urinary organs.

The next step is determined by what we have already learned from the history and physical examination, plus what the physical, chemical, and microscopical examination of the urine shows. If it seems likely that one or the other kidney or ureter is involved, the patient's bladder is explored with the simple prismatic cystoscope of the plain or irrigating type, as is indicated by the presence or absence of cloudiness in the urine.

When the patient is catheterized before we fill the bladder for the cystoscopy, this opportunity is taken to obtain by sterile means urine which can be subjected to bacteriological examination, if this is necessary.

By the cystoscopic examination we can pretty definitely determine whether the trouble lies in the bladder or above, and if the bladder is not the source of the trouble, we can still more definitely localize the disease by a careful study of the ureteral mouths and of the jets of urine emitted.

If, on the other hand, the bladder is the seat of the trouble, it will be unnecessary to collect the separate urines; and in such cases urinary separation and the use of the ureter catheterizing cystoscopes are contraindicated.

When we have gotten evidence that the lesion lies in the urinary tract, higher up than the bladder, and if we require for analysis the secretion of the individual kidneys, or wish to probe the ureters to determine their patency or advance a styletted catheter to get an *x*-ray picture, we then have the real indication for the cystoscope which has been especially designed for catheterizing the ureters. The use of this in the proper cases is crowned by the happiest results.

After the separate urines have been collected, the relative action of the kidneys noted, and the urines subjected to thorough analysis, chemical, microscopical, and bacteriological, we come to the point where good judgment and a knowledge of pathological anatomy are telling factors in the summing up of the evidence thus far obtained. Cryoscopy of the blood and urine and the phloridzin test, along with analysis of the separate urines, are means of estimating the functional ability of the kidneys. In cases likely to come to operation, steps to determine the status of the kidneys should be taken before we further consider nephrectomy.

It is only by such deliberate and methodical steps in history taking, in examination of the patient, physically and instrumentally, and in the complete analysis of the urine that we may hope to come to a satisfactory diagnosis.

616 Madison Avenue.

Professor Carl von Noorden, at present chief of the medical clinic at Frankfort-on-the-Main, has been called to Vienna to fill the chair made vacant by the death of Professor Nothnagel. Dr. von Noorden was in this country a few months ago and delivered several lectures on metabolism and on diabetes.

THE ADMINISTRATION OF DIPHTHERIA ANTITOXIN AND PERFORMANCE OF INTUBATION BY THE DEPARTMENT OF HEALTH OF NEW YORK CITY.

By J. S. BILLINGS, Jr., M.D.,

NEW YORK.

The administration of antitoxin in diphtheria was begun by the Department of Health in 1895, the antitoxin used being prepared in the laboratories of the Department.

A staff of physicians is on duty day and night in all boroughs of the city to answer calls for the injection of antitoxin, for curative and immunizing purposes, and also to perform intubation when necessary. When proper quarantine cannot be enforced, the Department removes the case to one of the Department hospitals. When a physician desires to inject the antitoxin himself, and yet the circumstances of the family are so poor that the purchase of antitoxin would be a hardship, he can obtain the antitoxin, free of charge, at the Department or at any of its culture stations throughout the city, by signing a certificate to that effect. He must, however, submit a history of the case on its termination. The Department has records of over 18,866 cases which have been injected with antitoxin furnished by it since 1895. Excluding the moribund cases, 1,325 died, a mortality of only 7.3 per cent. Cases treated early in the disease give almost no mortality. (The actual sanitary supervision of diphtheria, enforcement of quarantine, disinfection of premises, etc., is under the care of the Division of Contagious Diseases.)

Routine Procedure.—The city is divided into districts as follows: Manhattan, 12 districts; Brooklyn, 6; Bronx, 1; Richmond, 1; Queens, 2.

In Manhattan on Sundays and holidays the entire borough is covered by three inspectors, from 12 noon, Saturday, until 9 A.M. Monday, and on holidays from midnight previous to 9 A.M. the day following. These inspectors give primary injections for curative and immunizing purposes, reinjections when requested, take primary cultures, and perform intubation and extubation when the latter is requested by the physician. In Brooklyn, Queens, Richmond and the Bronx, the inspectors are on duty continuously.

Requests from physicians for the injection of antitoxin, for immunization or intubation, are received: (1) by telephone at the various borough offices (Manhattan, 4900 Columbus; the Bronx, 975 Melrose; Brooklyn, 4720 Main; Queens, 51 Jamaica; Richmond, 441 Tompkinsville). (2) By letter, visit in person, or postal card (there is a space for requesting injection on the card used for reporting a case of diphtheria). (3) By culture, the request being made on the culture slip. (4) By inspectors of the Division of Contagious Diseases, for cases under their sanitary supervision which are not receiving treatment. (5) Complaints.

Every such request is entered on a record card, the name, age, and address of the patient, the name and address of the physician, the hour received, and the nature of the request (injection, intubation, etc.). These cards form the record of the case. Every morning, information is obtained from each inspector, by telephone, concerning all new cases of the preceding twenty-four hours—hour visited, duration of the disease, location of lesion, amount of antitoxin given, and number of other children immunized. Each Monday the inspectors on duty for the preceding Saturday and Sunday fill out on cards all data of new cases seen by them, and also give the same information to the inspectors in whose district the patients reside. The cards are then filed under the name of the proper inspector; each Monday the inspector fills in all remaining data (death, recovery, dates of later visits, re-injections, etc.) on cards of all cases terminating during the preceding week. Completed cards are filed by date. Every three months the statistics are compiled for each borough. In addition a weekly record is kept of the total number of cases of and deaths from diphtheria in each borough, and the mortality. On receipt of a request for injection the call is telephoned at once to the proper inspector, the hour at which he was reached being noted on the card. Should the inspector be away from his office longer than three hours he calls up the borough office to learn if any calls await him. On receiving the call the inspector enters all data given in the notebook furnished him. Requests for injection are attended to within two hours. Requests for intubation or extubation are attended to at once. Immunization calls, if received after 6 P.M., may wait until the following morning. When immunization of large numbers of children (institutions) is requested, several inspectors are assigned to the work.

Each inspector is furnished with the following outfit: One black leather valise, containing vials of antitoxin; antitoxin syringe in case, with needles, and cannula; bottles of tincture of green soap, alcohol, and whiskey; silk for intubation tubes; absorbent cotton; sterilized gauze, cut in small squares; culture tubes, swabs and slips; safety pins; medicine droppers; hypodermic syringe in case with needles, and 1/100-grain strychnine tablets; diphtheria placards and intubation set. These bags are inspected once a month.

Antitoxin is furnished for the special use of inspectors in 10 c.c. bottles, containing 6,000 units. It is obtained from the Chief Clerk in each borough office between 9 A.M. and 4 P.M. At other times it is obtained at culture stations by signing a "free slip." In Manhattan it can also be obtained between 9 A.M. and 4 P.M. from the office of the Division of Contagious Diseases. All other supplies are obtained from the Inspectors in charge of the borough.

On reaching the case the syringe and needles are boiled in the case provided for that purpose, and allowed to cool before antitoxin is drawn into them, otherwise it will coagulate. The preferable site of injection is into the loose cellular tissue of the lateral abdominal wall or the loin. The site is washed with tincture of green soap, followed by alcohol. The skin and cellular tissue are caught up between the thumb and fingers and the needle is inserted laterally. The injection must be made slowly to avoid subsequent abscess. Upon withdrawal of the needle a wad of cotton, wet with alcohol, is fastened over the puncture with adhesive plaster. The amounts of antitoxin given are as follows: Under 2 years, from 3,000 units; over 2 years,, from 5,000 units and upwards. In severe cases, especially those complicated with bronchopneumonia, possibly caused by the diphtheria bacillus, massive doses of 20,000 to 40,000 units are given.

In giving antitoxin for immunizing purposes the same precautions are adopted as above, except that the needle need not be resterilized between children in the same family. For immunizing purposes the dose is: Under 2 years, 300 units; over 2 years, 500 units and upwards. This should protect from two to three weeks. As many immunizations as possible are done, not only in the immediate family of the patient, but in the other families on the same floor and in the same house. This is to prevent the

spread of the contagion, which is as important as the cure of the original case. (Since January 1, 1895, immunizing injections of antitoxin have been administered to over 21,000 individuals by the Inspectors of the Department of Health, and by physicians (free cases only). Of these individuals 65 (0.3 per cent.) contracted diphtheria of a mild type; one case only terminated fatally). The character of the work of the inspectors is judged as much by the number of individuals immunized than by the number of cases treated or by the result of such treatment.

A culture is taken at the first visit in each case unless it is certain that it has already been done by the attending physician or the Inspector of the Division of Contagious Diseases. If before 4 P. M., this culture, with properly filled out slip, is left at the nearest culture station, a list of which stations is carried by each inspector. After 4 P. M., the inspector brings or sends the culture to the Borough Office, where it is put in the incubator.

In all cases of diphtheria (except those in private houses or hotels), when it has not already been done, the inspector affixes a placard to the door.

Every patient is revisited the day after injection (to reinject if necessary) and again on the day after reinjection; on the fourth day (in severe cases), and on the fourteenth day, to ascertain the occurrence of rashes, sequlæ or complications, cause of death, etc.

Injection is never refused in doubtful cases, but with the consent of the attending physician it may be postponed twenty-four hours to await the result of examination of culture. At the request of the attending physician doubtful cases are considered and treated as true cases of diphtheria. In cases in which the necessary quarantine is wilfully disregarded or cannot be observed, the inspector recommends that the patient be removed to a hospital. If the family's consent is obtained, the Division of Contagious Diseases is requested, by telephone, to send a diagnostician. In Manhattan such patients go to the Willard Parker Hospital, in Brooklyn to the Kingston Avenue Hospital, in Richmond to the Smith Infirmary, and in the Bronx to the Riverside Hospital.

Every diphtheria patient requiring intubation, where the attending physician is not familiar with the operation, should be removed to a hospital where it may be watched and the tube immediately removed or replaced as occasion arises. The inspector urges such removal in every case; when consent is not obtained from the physician or the family, warning of the possible dangers is given. The Department of Health does not hold itself responsible for such cases. Attending physicians, when requesting intubation, are notified that they must be present at the operation, as otherwise the patient may be removed to the hospital if deemed advisable. When the proper inspector cannot be immediately obtained to answer requests for intubation, the call is telephoned to a Department Hospital, whence an ambulance and physician are sent. In all cases intubated by the hospital physician, whether removed to hospital or not, the inspector does the necessary immunizing, placarding, culture taking, etc.

Each inspector receives thorough instruction and practice in intubating, under the guidance of a skilled instructor. The intubation set furnished includes the following: Gag, introducer, extractors (2 sizes), set of tubes (1-year, 2-year, 3-year, 4-year, 5-year, 10-year), with obturators. The hand bag contains the other necessary articles. Extra tubes with obturators are kept on hand, as follows: 3 one-year size, 3 two-year size, 1 three-year size, 1 four-year size, 1 five-year size. Each obturator is specially fitted to its tube, and is to be kept in the same. A tube must not be used with a misfit obturator. All tubes must be kept constantly threaded with 18 inches of silk thread.

The fine corrugations on the jaws of the extractor should be distinct and rough to the touch. The jaws of the gag should be smooth and the notches in the holder clean cut. The introducer must always be moistened with a drop of oil at the slide.

The indications for intubation are: Labored or insufficient respiration, cyanosis, dilatation of the alæ nasi, insuction of the supraclavicular spaces and violent action of the diaphragm.

From the patient's family are obtained a plain wooden kitchen table, a clean sheet folded so that it will reach to the child's shoulders and overlap when tightened around the child, and a basin of hot water. An assistant to hold the head is necessary. The child's clothing is removed down to the waist, and the patient is placed flat upon the back upon the sheet, which has been laid on the table. The sheet is then wrapped snugly about the patient, reaching from the shoulders down, confining the arms to the sides. It is fastened by safety-pins inserted along the far side of the patient. The assistant holds the patient's head, with chin well up, firmly with both hands. In children over 1 year the gag is then inserted and opened widely. The introducer, fitted with a tube of proper size, is taken in the right hand, letting the string dangle. The left forefinger is inserted into the pharynx until it reaches the epiglottis, which it pushes out of the way. The tube is then introduced, following the left finger as a guide. The cap of tube is held with the left finger tip and the introducer is withdrawn. The finger is then withdrawn, the gag loosened, and the throat swabbed out with a gauze square. If the tube is properly inserted the child will breathe better immediately and start to cough with a characteristic metallic sound. If the cough is insufficint a drop of whiskey and water, introduced by a medicine dropper, will accelerate it. In a few minutes, if everything is satisfactory, the ligature is removed. (This is done by reinserting the finger, cutting off the knot, and holding the cap while the string is pulled out.) The gag and sheet are then removed. Skillful intubation should not take more than three seconds. Avoidance of any of the above routine will not hasten the performance of intubation.

Rules for inspectors—

1. Exchange of Sunday or holiday assignments can only be made after obtaining consent of Chief of Division or Inspector-in-Charge.

2. Special reports must be made on the proper blank.

3. In filling out culture slip, write correct name and address of attending physician legibly.

4. Antitoxin must be kept in a cool place; never in the pocket or bag over night. A bottle once opened must never be used subsequently. Empty bottles must be returned at intervals to the borough office.

5. The intubation set must be kept in perfect order and ready for use. After performance of intubation all instruments must be washed and boiled before being returned to the case.

6. Intubation tubes must be accounted for. When the patient goes to a hospital with tube in throat a report of all essential facts must be made at once so that the tube may be recovered. Tubes in "at-home" cases must be recovered by the inspector. In case the patient dies with the tube in the throat, it is not to be removed.

7. If the inspector fails to find the patient at the address given, he must obtain the correct address at

once from the attending physician, using the nearest telephone.

Note.—Diphtheria antitoxin is furnished by the department through its culture stations (list on application), free of charge to physicians, under the following conditions:

1. The physician must sign a certificate to the effect that the family of the patient is unable to pay for the same.

2. On termination of the case by death or recovery he must forward a history of the case on the blank furnished for that purpose. Should he fail to do so the history is requested by letter.

These histories are tabulated at the end of each year.

A circular is issued which gives full information as to the causation, mode of spread, prevention, and treatment of diphtheria. This is distributed to physicians throughout the city

32 East Fifty-third Street.

THE NON-OPERATIVE TREATMENT OF PROSTATIC HYPERTROPHY.*

By WALTER S. REYNOLDS, M.D.,

NEW YORK.

CLINICAL ASSISTANT IN GENITOURINARY SURGERY, VANDERBILT CLINIC; ATTENDING SURGEON AND INSTRUCTOR IN GENITOURINARY DISEASES, UNIVERSITY BELLEVUE COLLEGE.

Within the last few years newer methods of operative treatment for prostatic hypertrophy have come into vogue, and much has been added to our knowledge of the condition by the interest and study thus excited.

The condition is one so frequently an accompaniment of advancing years, giving rise to such distressing symptoms in many cases that it appeals to us all for relief, and any measure which offers a cure must therefore be warmly welcomed. Our enthusiasm, however, should not cause us to forget that the more conservative methods of treatment may often bring relief to these patients without subjecting them to an operation which still has a mortality of three per cent. or over, and in which the results are not always ideal.

In almost every medical journal nowadays will be found an article recounting one or more operations for the relief of the symptoms accompanying this condition, showing how eagerly the operation has been taken up. A careful reading of many of these cases will show that the improvement hoped for has not always been realized, and in some cases the patients have been left in a worse condition than before operation. These results are from published cases; bad results are apt to be withheld. In the *American Journal of Urology* recently Dr. Whiteside of Portland, Ore., has collected a number of these cases, and gives a very complete analysis of their condition after operation. It is unfortunate that an operation which theoretically should give such good results fails in its performance in such a considerable proportion of cases. The bad results can in some instances probably be accounted for by the inexperience of the operator. More often it is due undoubtedly to improperly selected cases, and in many instances largely to lack of sufficiently prolonged preparatory treatment.

Patients should not be urged to operation before systematic treatment has been tried, unless some particularly positive indication requiring it exists. The symptoms are not alone due to the enlargement of the prostate, and so much can be accomplished for these patients by careful and well-directed treatment, for the relief of their symptoms, that it is right that these measures be given fair trial before operation is too urgently insisted upon. Even though nothing more is accomplished by treatment the patient is placed in a position to make his recovery from operation easier and smoother.

Pathologists now seem pretty well agreed that prostatic hypertrophy is due to inflammatory changes, having their starting point in the glandular structures, and thence spreading to the interstitial parts. Clinical evidence seems to bear this out, as in the early stages the prostate is often found to be soft and boggy, with evidences of a catarrhal prostatitis.

While it is undoubtedly true that gonorrhea is a very important factor in the production of these changes, there are, no doubt other causes, as prostatic hypertrophy is found in patients who have never had gonorrhea. Any one who will read Dr. Bangs' very able article on this subject cannot fail to be convinced of the correctness of his conclusions. It is only necessary to question carefully some of these people to learn how frequently other factors may be of etiological significance. Prolonged congestion or hyperemia of the structures in and about the deep urethra results from abnormal sexual habits, which, if kept up sufficiently long, may be productive of pathological changes. Masturbation, sexual excesses, pernicious sexual habits invented to gratify a perverted or exhausted sexual appetite, to prolong its pleasures, or to prevent the fulfillment of nature's laws have one or all a place in the history of these cases.
